Zero power. End of story. But Cecil claims there's more:

> Those two waves engage in wave cancellation but the energy in those
> two waves cannot be canceled. It changes direction and joins the
> forward wave. I am trying to find out the official name of that
> mechanism.

Totally unsupporable speculation. There exists no mechanism in nature
that would produce such a "change in direction". The truth is the waves
do not form due to field cancellation, no energy is transferred in the
reflected direction, and the incident energy procedes to the load.

> > Similarly, Pfwd2 = 75W + 8.3W = 83.3W and not the Pfwd2=133.33W you cite
> > above.

> Since the 50W contained in the canceled waves changes direction, we
> get Pfwd2 = 75W + 8.33W + 50W = 133.33W

No. You get 133.33W in the forard direction because
75W + 8.33W + 2*sqrt(75W*8.33W)= 133.33W. That's the correct equation
for the superposition of the two waves propagating in the direction of
the load.

> The -50W is destructive interference, The +50W is constructive interference.

Your equation produces a negative value for something which can have
only positive values, and is indicative of an error in your calculation.

> The Conservation of Energy principle is satisfied.

That would remain true no matter what anyone might happen to say on the
subject.

Jim Kelley wrote:
> No power or energy is reflected from the discontinuity in a matched
> system, by definition.

Correction: No *NET* power or *NET* energy reaches the source in a matched system. There's plenty of reflected power as proven by the s-parameter equations. You know we are *NOT talking about *NET* anything. Why do you want to continue to beat that old dead horse? We are talking about the component energies that cause the *NET* result.

b1 is the *NET* reflected voltage and is indeed zero for a matched system. b1 = s11*a1 + s12*a2 so it is more than obvious that there are two reflected voltage components associated with the net b1=0 voltage.

> Obviously you aren't following the topic very closely. a11 is
> not a network parameter. It's a port parameter for one of the ports.

:-) s11 is the reflection coefficient, (Z1-Z0)/(Z1+Z0)

> The energy never travels rearward after the transient period.

Of course it does, Jim. Energy always travels rearward from a mismatched load. Standing waves wouldn't exist without the reflected energy traveling rearward from the load. So you next assertion must be that standing waves don't exist or demonstrate how they can exist without reflected waves.

How many times are you going to deny the reality of reflected waves being one of the absolutely necessary causes of standing waves?

Source record: 113847

Jim Kelley wrote:
> The waves DIDN'T EXIST.

If the reflected wave didn't exist, then no standing waves could possibly exist.
But standing waves do exist so your assertion is false. Therefore, a reflected
wave exists between the mismatched load and the impedance discontinuity.

> No. I'm simply describing the physics, and the math.

You are describing your wet dreams. If your boss could see the bafflegab
that you are posting, you would probably be fired for incompetence.

> Wave cancellation prevents energy from being reflected, ...

Wave cancellation prevents energy from flowing toward the source.
It does that through the destruction of two reflected waves, one
of them from the mismatched load. We know the reflected wave from
the mismatched load exists because it causes standing waves. Therefore,
your premise is false.

Your out of context quotes from physics books are definitely bafflegab.

Here's a quote out of my physics book, Jim. deltaP2 = -deltaP1 That equation proves I am right and you are wrong. See, I can do it also. Do you agree with that equation or not?

(Power In = Power Out) at a lossless impedance discontinuity incapable of storing energy is the same thing as stating that energy cannot be created or destroyed - exactly the same thing. It is unfortunate that you don't realize that fact.

>>That applies to any system around which
>>you can draw a boundary.
>
> A closed system is a pretty specific sort of thing. You can't just
> arbitrarily draw boundaries and then claim that energy must be conserved
> within them.

Of course you can, Jim. You can draw arbitrary boundaries anywhere in the universe and bet that the energy must be conserved within them. Does your boss know you are uttering complete bafflegab on this newsgroup advocating violations of the accepted laws of physics?

> The energy is not destroyed because V3 and V4 do not "materialize" in
> the first place.

You're too late, Jim. V4 has already materialized at the mismatched load and traveled back through the impedance discontinuity. If you do nothing with it, it will be incident upon the load. Given V4 has existed for a few nanoseconds already, exactly how are you going to talk it into dematerializing just because your wet dream wants it to?

It is not a question of something not materializing. It is a question of canceling something that already materialized at the load and traveled all the way from the load through the impedance discontinuity.

>>
>>Adding those two waves together yields zero volts and zero amps.
>
> Zero power. End of story. But Cecil claims there's more:

Let's expand your false statements to make them true. There is zero
NET energy flowing in the direction of the load because of the destruction
of the two reflected wave components above.

We know that one of the wave components exists because it made a trip
from a mismatched load all the way back through the impedance discontinuity.
If it didn't exist, then it couldn't possibly have caused any standing waves,
but we know it did. Therefore, your premise is wrong. If it didn't transfer
any energy, it couldn't possibly cause standing waves, but it does.

That wave reflected from the load cannot disappear all by itself. It
takes another wave of equal magnitude and opposite phase to make it
disappear. Therefore, two waves exist.

We know the wave reflected from the load contains energy. We know it
is destroyed at a point. What happens to its intrinsic energy? Energy
cannot be destroyed. Energy doesn't make it rearward to the source.
There's only one possible direction - back toward the load just as
described on the Melles-Griot web page.

> There exists no mechanism in nature
> that would produce such a "change in direction".

It is possible that man has never defined such a mechanism but we know it
exists. Human knowledge is not 100% accurate or complete yet, Jim, even
if your omniscient syndrome believes yours to be. If the mechanism has really
never been defined in physics, it is my goal to define it. I'm still
thinking it has been defined and you are just ignorant of it.

> No. You get 133.33W in the forard direction because
> 75W + 8.33W + 2*sqrt(75W*8.33W)= 133.33W. That's the correct equation
> for the superposition of the two waves propagating in the direction of
> the load.

Yes, that's the correct equation where 2*sqrt(75*8.33W) is known as the
"interference term". Why do you think they call it the interference term,
Jim? Maybe because it *IS* the constructive interference term and according

to Hecht, an equal magnitude of destructive interference must exist on the other side of the impedance discontinuity? Destructive interference caused by the destruction of two reflected waves?

> Your equation produces a negative value for something which can have
> only positive values, and is indicative of an error in your calculation.

It's not negative energy, Jim. Destructive interference is energy rejected from the interference process. The rejection *direction* is why it is negative. Constructive interference is energy required by the interference process from the direction of the destructive interference. That's why it is positive. But the convention could just as easily be reversed. Either way, the destructive interference needs to carry the opposite sign of constructive interference, not because the energy is negative, but simply to denote direction of flow, which is a commonly accepted practice. If current is flowing to the left, is it negative current? Get real!

>>The Conservation of Energy principle is satisfied.
>
> That would remain true no matter what anyone might happen to say on the
> subject.

Actually, you violate the spirit of the Conservation of Energy principle quite frequently. Good thing it all happens in your mind.

You can't have it both ways, Jim. If, as you say, reflected waves transfer no energy, then they couldn't possibly cause standing waves, but they do. It takes energy to cause standing waves.

Now that you mention it, your model is rather like that of the
geocentric model of the universe. :-)

> > you can add currents, and you can add voltages, but you can not just add
> > powers.

> Hmmmmmm, you believe we cannot add scalar values? How about one quart of
> water plus one quart of water?

Don't you mean minus one quart of water plus one quart of water? (One
of the quarts undoubtedly changes direction in order to join with the
quart moving in the forward direction.) :-)

> Follow my logic and
> see if you can find a mistake instead of completely dismissing everything > without a
second thought.

Your mistake is the assumption that energy is reflected when it is not,
and then being forced to make up for that mistake by claiming the energy
reverses direction by re-reflecting without encountering a boundary from
which to re-reflect.

Faith is the only thing which might support such a belief - not unlike
the faith held by the Catholic priests of Galileo's time.

Doc, you can give but not take
He is correct..When Richard made a snide remark you took the
oportunity to jump in behind him with one too. Nothing technical
you just jumped on the bandwaggon.
And now you complain because somebody jumps on you.
He is correct you NEVER provide any technical insight
only "me to " comments. Well now you have the thread all to
yourself until Richard comes up with something like a new
thread but with the same title again....and again...and again.
Bye Bye

A valid question. The answer is that energy is indeed transferred between the load and the match point during the transient period, setting up the standing waves between those two points. But additional energy is not required to maintain the oscillations on the transmission line during the steady state as no energy is transferred in that direction beyond the match point, nor is that portion of it re-reflected by the match point. The oscillations are simply maintained on the transmission line by the wave which is incident upon the load boundary. You're incorrectly presuming these oscillations represent a transfer of energy, but it is clearly seen that no path exists to enable or facilitate such a transfer.

> > No. I'm simply describing the physics, and the math.

I have regular discussions on this subject with my colleagues, and my facts are indeed being checked by knowlegeable folks. I think you even know one of them. My interest here is in physical phenomena.

> > Wave cancellation prevents energy from being reflected, ...

That's what I've been saying. There is therefore no need for it to "change direction".

Well, it's part of the equation. Same equation I first posted here on
the newsgroup. I quoted it right from Born and Wolfe. How does that
make me wrong?

> clears up too.

The best way is with as short as possible heavy braid to a system of
interconnected 10 ft copper ground rods.

An acceptable way, especially for receiving only, is to a simple ground
rod, or to a water pipe (provided the pipe is grounded). Even grounding
to the electrical power ground can help.

You cannot arbitrarily draw a boundary and expect that energy will
necessarily be conserved within that boundary. Sorry. If you really
knew what you were talking about, you would know better. Draw a boudary
around a power plant and try proving energy is conserved within the
bounded system.

Also true.

> There's plenty of reflected power as proven by
> the s-parameter equations.

When solved as a network, the s-parameters show that the voltages cancel, and that the reflection coefficient of the network as a whole is zero. When you ignore most of the network then you arrive at partial solutions.

> > Obviously you aren't following the topic very closely. a11 is
> > not a network parameter. It's a port parameter for one of the ports.

> :-) s11 is the reflection coefficient, (Z1-Z0)/(Z1+Z0)

for one of the two ports. There are two ports AND a load - all of which determine the network characteristics.

> > The energy never travels rearward after the transient period.

> Of course it does, Jim. Energy always travels rearward from a mismatched
> load.

It's mismatched if we pretend the matching network isn't there. But it is there. You seem to believe it has no effect on the waves between there and the load.

> Standing waves wouldn't exist without the reflected energy traveling
> rearward from the load.

The fact that they do should be cause for some reconsideration of your point of view. How much energy do you contend it takes for the transmission line to store the amount of energy transferred there during the transient period? That is the amount of _energy_ that was reflected back to the discontinuity by the load. It remains the only energy unaccounted for in the steady state energy analysis.

But that is impossible. Standing waves cannot be maintained without
reflected waves. You are once again beating the *NET* energy dead horse.

> You're incorrectly presuming these oscillations represent a transfer of

> facilitate such a transfer.

Standing waves are impossible unless the reflected waves contain energy.
If standing waves exist, your premise is false.

> That's what I've been saying. There is therefore no need for it to
> "change direction".

Since half of the energy flowed rearward from the mismatched load,
you are just blowing smoke.

As long as you reject the wave reflection model, we will have nothing
left worth discussing.

"Left again."

It`s a fact. Lightning is easily imported via a wire to the outside of a protective enclosure.. It`s similar to the way in which noise is leaked in or out of a screened room.

As the outside of the coax should be grounded anyway, it is simple enough to soundly connect the coax shield at its entry point to the metal enclosure, and all done! The same lightning potential is distributed to all sides of the enclosure, leaving little difference of potential between any sides. Hazard has been avoided.

All energy is conserved. Do you think energy will be destroyed or created
within that boundary just because you will it to be?

> Prove it. Measure V4 on the front side of the impedance discontinuity.

I've done that, Jim. V4^2*Z0 is what heats up the circulator load resistor.
If reflected waves transfer no energy, how does the reflected wave heat
up a resistor?

The reflection coefficient is s11 = (Z1-Z0)/(Z1+Z0). So says the
HP AN 95-1. Sorry about that. Your "reflection coefficient of the
network as a whole" is NOT a physical reflection coefficient and
is only a mathematical construct.

>>Energy always travels rearward from a mismatched
>>load.
>
> It's mismatched if we pretend the matching network isn't there. But it
> is there. You seem to believe it has no effect on the waves between
> there and the load.

You are in a room with a hole in the wall. Through the hole comes a 150
ohm feedline. The load on the feedline is 50 ohms. The forward power is
133.33W and the reflected power is 33.33W. Is the system matched or not?

You say if it is matched, there is no energy in the reflected wave but
if it is not matched, then there is energy in the reflected wave. Again,
I ask you: Where do you find waves smart enough to know whether to carry
energy or not and where do you find waves that obey your telepathic thoughts?
Are you the reflected wave God?

Hint: The above conditions are *identical* whether the system is matched
or mismatched. ***YOU*** are not smart enough to tell the difference so
how the heck are the waves smart enough to tell the difference?

This discussion is not about solutions provided by math models. I am
interested in what happens in physical reality.

So here's a question for you. What mechanism of physics keeps a
physical impedance discontinuity from causing a reflection from the
incident wave? Please be specific.

>
>
>
> I think maybe now we have the definitive answer to the original inquiry!

Not the one you think.
Lightening is unpredictable.
AT most the ungrounded portion of the radio chassis can be no more
above ground than the breakdown voltage of the lowest common
denominator (plus the rise time and allowance for resistance)... That
the lightening, or rather a portion of it followed the coax to the
radio and then to ground (inside the radio) with spectacular results
is no indicator of indangering the passengers in the car. (unless it's
from heart failure.) It's unlikely the voltage that made it to the
radio was of any great magnitude, but it contained the ability to
provide very high amperage which could vaporize most of the radio.

I've been a storm chaser for over 25 years and have yet to worry about
lightening when in the car. I do have great concern when standing
beside the car with an approaching storm. Lightening can easily
strike 10 to 15 miles ahead of the storm out in clear sunshine which
is far more dangerous than driving through an area of intense cloud to
ground lightening.

A few years back I was flying from Midland Michigan (3BS) to Houghton
Lake (HTL). Gladwin (GDW is just about half way in between on a
straight line.

When we departed Midland I noted a big thunderstorm approaching
Gladwin from the west. So I headed straight north, expecting our
course would run about 15 miles east of the storm.

As we were passing due east of the storm my friend (a ham and also a
pilot) asked me how close we really dared get to a storm like that. I
was just about to answer when a bolt shot out horizontally and

directly at us at 5000 feet. About two miles to the west of us it curved down and hit the ground.

I looked at my friend and said, "You were asking what?". He remarked that he thought he'd just received one of the most remarkable answers he'd ever seen.

I have been in situations where I have a far greater concern about hail whether in a car, or airplane than I've ever had about lightening.

One other occurrence. My neighbor from across the road and I were standing out front at the end of the driveway. There was a thunder storm approaching and we were wondering just how far away it was. I had been counting and figured the last strike was about two miles from us and that meant we should probably get inside.

I'd no more than finished the sentence when lightening stuck the power pole about 20 feet from us. We bailed.

Is there a risk to lightening while in a car? Yes. How great? I don't know due to the unpredictability of lightening, but the odds are heavily weighted in your favor.

I haven't bothered disconnecting my outside antennas at the home station for years and they are the highest things around. 144 and 440 arrays at 130 feet, 7L on 6 at 115 feet, Hygain TH-5 at 100 feet, two slopers for 75 and one for 40 at 90 feet, a 144/440 Diamond repeater antenna with the base at 55 feet and a 40 meter inverted V at 45 feet.

That system gets hit an average of three times a summer. I haven't lost a radio in years.

As I said in another post. Lightening "to me" is not a concern when driving, or in the car except when I was driving a TransAm (Plastic car). <:-)) Other than the roll bar your head is the highest conductive thing around in that case.

Not only the flash over at the base, but I'd bet the capacitance at
the base to roof would offer a much better path than the inductance of
the coax into the car. That stuff has a huge Dv/Dt, or Di/Dt if you
wish to measure current rise.

I've seen lightening strike a large, grounded tower and get off part
way down. The inductance and counter EMF was enough to quench the
arc, causing it to seek an easier path. Just stop and think about how
intense that magnetic field had to be.

I was given the traps and baluns to a Spi-Ro antenna. The wire connecting the traps and the balun have been cut and discarded. I am looking for some information on the wire lengths and "general" information on this antenna. It appears to match a VS-64 antenna that covers the 10,15,20,40,80,160 bands on their web page. I have one balun, T-15, T-20, T-40, and T-80 traps. Does anyone have any specs for this antenna. I have sent an e-mail to Spi-Ro but have gotten no response. Thanks.

Dale Parfitt wrote:

> Could you explain why grounding the dipole helps?

Grounding the entire system helps, not (necessarily) the antenna itself, by reducing the noise level. A single point ground for all the electronics in the shack makes a hell of a difference. My RX noise level rises some 10-15 dB when I untie the grounds from the RX, PC, keyer, amp, p/s, etc.

Spencer:

When you are dealing with rocky soil (or solid rock like where I live) you need to get a bit creative...

Generally, with rocky soil (or living on rock) you will not be able to pound a ground rod into the earth to get what you expect for a ground.

Unfortunately, many people living on "normal ground" rely on a single ground rod, which also reduces their ability to adequately ground their antenna system.

There are different needs for grounds for transmitting/receiving compared to grounds for lightning protection, though generally speaking, a good ground system for lightning protection does a fair to good job for hf transmitting/receiving as well.

Where I live (Hawaii) the ground is nearly solid lava, which is both a poor conductor and very very difficult to drive anything into... With a decent air hammer (Jackhammer?) you might be able to chisel a hole a few feet deep that you could pound a ground rod into, but you won't get the ground rod very deep, no matter what you do. (Think about trying to drive a ground rod into solid granite and you get the idea. Despite the fact that lava is typically pretty porous relative to water, it is a bear to try to drive anything into it...)

Think about burying radials a few inches below the soil line, or even placing them on the surface, and letting the lawn (grass, or other landscaping, or even weeds) take over and cover the wires.

When I built my workshop/studio, I placed about a thousand feet of 12 gauge wire below the vapor barrier, before the concrete was poured. It was oriented as a grid on about 5x5' covering the area of my workshop, about 32x52 feet. The individual wires are joined as they exit the concrete at a common point near the area I use for my Ham Shack. Even though none of these wires are intentionally resonant at any of the HF frequencies I use (160 to 10M), they seem to make a very effective ground system for every antenna I have tried in this location so far.

With your rocky soil, you may need to do something similar, even if you aren't planning to put up a large workshop. Get a bunch of wire at or below ground level, tied together at a common point, and give up on the "standard" 8' driven ground rod. It is typically an artifact of code requirements for AC service and not typically all that effective at HF frequencies anyway.

If you can't get out a decent grid of wire, at least consider a tuned counterpoise, (where you have at least one wire that is a quarter wavelength for each of the frequencies you plan to use) running from a common point near your shack.

However you do it, generally speaking, more is better. If all you can do is to connect to your in-house ground via a buried copper or galvanized water pipe, at least it's something. Replacing that with a tuned counterpoise or a fairly extensive grid can only help, though depending upon your circumstances, the improvement may not necessarily be worth the cost or effort....

Thanks

Michael:

Unless I am mistaken, every transmission line/antenna system will have some standing wave pattern as you change the frequency... I can't imagine any system that wouldn't have some sort of standing wave pattern as you sweep from low to high frequency (Except perhaps a pure, non-inductive resistance, which isn't typically much of an antenna).

You may want to qualify your request somewhat so we can respond appropriately. Please provide the frequency range you expect to work, the amount of space you have available, and any other information that might affect the selection of the antenna/system that we would need to suggest. As you indicate, a Bazooka has "no where near the bandwidth" you are thinking of, so how about telling us the bandwith you want??? It is possible you could get a much more meaningful answer.

Thanks

[snip]

But "standing waves" are a purely steady state phenomena and according to
your recent
postings the steady state cannot exist.

On the other hand, "standing waves" cannot exist without a "steady state".

Until you accept that there is a "steady state" there can be no "standing
waves" and hence
there is no energy required to initiate and sustain those "standing waves".

In the transient state there are no standing waves and so one doesn't need
such specious arguments.

What?

Roger, K8RI wrote:
"I`ve seen lightning strike a large grounded tower and get off part way down."

I`ve no doubt that happens. I know, however, that some strokes make the trip nearly all of the way in large part, from my years in broadcast stations.

Broadcast stations use transformer coupling to their towers. A grounded metal picket fence (Faraday screen) is inserted between primsary and secondary coils. Purpose of this shield is elimination of electrostatic coupling between transmission line and tower. Electrostatic coupling would favor harmonics of the broadcast frequency.

The Faraday screen is also the most effective lightning eliminator around. Any station`s screens I`ve seen were richly pitted from the many lightning strikes experienced.

Examination of the arc-gaps of the associated tower base insulator reveals pristine paint in most cases. Makes one wonder, why bother with gaps when you have a Faraday screen? It`s tradition.

Though little lightning may make it to the r-f transmission line, the transient it induces may cause an r-f arc in the transmission line. This hair-lips the signal and if sustained can damage the transmitter. To kill the arc, it is necessary to momentarily kill the transmitter. Automatically, this is usually accomplished by isolating the transmission line for d-c. A d-c supply with a relay coil in series is placed across the transmission line. When an r-f arc completes the path across the transmission line for d-c, the relay is energized removing the transmitter from the air for an instant, thus killing the arc.

Point is, the effects of lightning sometimes make it all the way to the radio.

Best regards, Richard Harrison, KB5WZI

Cecil,

If you set up the condition that on the left side of the discontinuity
that the two "waves" cancel each other, which results in no energy in

Pref1, then there is some cancellation of the waves on the right side of the discontinuity. On the right side of the discontinuity, there is 75W which came throught the discontinuity and a cancelling 8.33W (33.33W-25W). Hence, my calculation of energy on the right side is 66.67W.

Plugging this in to your equation, I get

- [0 - 100W(0.25) - (-33.33W)(0.75)]
= 66.67W - 100W(0.75) - (-33.33W)(0.25)

- [0 - 25W - (-25W)] = 66.67W - 75W - (-8.33W)

- [0] = 0

44. Cargo container of Antenna Tuners. ID?

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-01 13:09:37 UTC
From: RF_AUDIO@collectiblehelp.com
Message-ID: <f3d277fb.0307010509.398f6640@posting.google.com>
Source record: 113788

Group,
I found a cargo container of these "OLD" Mil Aircraft antenna tuners.
I bought 3 truck loads of other old tube gear from these folks but
passed on these tuners.
No body knows what they tuned. TRAILING WIRE? I think they are MF/HF.
Inside are 2 vario-ductors or (vario-couplers),
fixed caps, lots of HV ceramic switches. Coils are old cloth litz wire
on bakelite/fiber core forms.
They are extreemly lightweight for their size. Transmitter Tuning Unit
TU-10-B

Can these be used for anything worthwhile or just junk?
Maybe too narrow banded for Amateur use?

Maybe a veteran or aircraft radio buff recognizes these.

Here are 3 of them->
http://pic3.picturetrail.com/VOL18/68355/167687/28486943.jpg

I took a sample unit apart to inspect.
I have to buy the whole container or pass.
They are kind of neat, but that is a lot of tuners to get stuck with.
Even at $2.50 ea prox.

Thanks for reading,
John

Standing waves certainly exist with modulated waves which are not steady-
state. Feed a TV receiver with 1000 ft of open-wire line. You have ghosting
indicating there is no steady-state AND you have measurable standing waves.
So your following premise is wrong. Please try again.

> On the other hand, "standing waves" cannot exist without a "steady state".

Not "cancellation" on the right side. It is "enhancement" on the right side, i.e. destructive interference on the left side and constructive interference on the right side. You have a sign wrong in the following.

> On the right side of the discontinuity, there is 75W
> which came throught the discontinuity and a cancelling 8.33W
> (33.33W-25W). Hence, my calculation of energy on the right side is 66.67W.

The 8.33W is enhancing, not canceling. You have the sign wrong.

> Plugging this in to your equation, I get
>
> - [0 - 100W(0.25) - (-33.33W)(0.75)]
> = 66.67W - 100W(0.75) - (-33.33W)(0.25)

Using the correct sign:

- [0 - 100W(0.25) - 33.33W(0.75) = 133.33W - 100W(0.75) - 33.33W(0.25)

-[0 - 25W - 25W] = 133.33W - 75W - 8.33W

- [- 50W] = +50W

If there is cancellation (destructive interference) on one side of the impedance discontinuity, there will always be an equal magnitude of enhancement (constructive interference) on the other side of the impedance discontinuity. _Optics_, by Hecht says that must be true to satisfy the Conservation of Energy principle.

They are tuning units from BC-375 and BC-191 Radio transmitter
sets designed in the late 1930's and used in B-17, B-24, B-25
and B-26 aircraft. Tuned from 150KHz to 21MHz using various
plugin tuning units, they were made by various manufacturers
(GE, WECO, etc.).

Pictures of complete radio sets:
<http://vrza.dse.nl/wc52/radios.html>
<http://www.kwarc.on.ca/hammond/waryears.html>

Here are some units that have sold recently on eBay.

There was a PBS documentary on this several months ago I happened to see. Through the modern wonders of sferics and WAN work they were able to document a fascinating and yet very sad story from horizontal lightning in clear air. Per this documentary, a golfer was killed on a course in Colorado from a lightning hit in completely clear air and no storm anywhere they could see.

However, the exact time was noted, and a comparison, in this case, could be made with the area sferics WAN system. At that time there were very few possibilities for this strike, The actual hit could be verified in the system for the unique time involved. The source of the strike was absolutely confirmed, per this TV doc, to be some TWENTY miles away! The strike had traveled some TWENTY miles in clear air before killing the poor fellow on that golf course.

You're just adding more proof you don't understand the difference between an equality and a law of nature.

> > You cannot arbitrarily draw a boundary and expect that energy will
> > necessarily be conserved within that boundary.

> All energy is conserved. Do you think energy will be destroyed or created
> within that boundary just because you will it to be?

It has nothing to do with me. It's amazing to me that you aren't imbarassed to make such statements in a public forum. Energy is not necessarily conserved within any arbitrary boundary. Your notion of energy conservation is sophomoric.

> > Prove it. Measure V4 on the front side of the impedance discontinuity.
>
> I've done that, Jim. V4^2*Z0 is what heats up the circulator load
resistor.

:-) There is no circulator in the circuit we're discussing. If there was, it would be a different circuit and it would behave differently. Don't you know that?

> If reflected waves transfer no energy, how does the reflected wave heat
> up a resistor?

Obviously the circulator load resistor heats up when energy IS reflected. The circulator load resistor does not heat up when the source matches the load, but inserting a circulator between the match point and the load causes reflections between the source and the match point. There would no longer be an impedance match between the source and the load. Get it?

52. Effect of materials on path loss?

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-01 16:17:37 UTC
From: achilles03@hotmail.com
Message-ID: <fef44ceb.0307010817.2d12a37a@posting.google.com>
Source record: 113796

What are the major factors that contribute to path loss through different mediums/materials? For instance, I know moist air has a higher path loss than dry air.

The reason I ask is that I'm debating whether to transmit from inside an enclosure that is primarily styrofoam (1.5" thick), or if I should make accomodations to extend the antenna beyond the envelope of the container.

Thanks in advance for any advice or insight anyone can offer!
Dave

Wes, KC8SPR wrote:
"If so, how?"

Two coils sharing the same axis and near each other will be closely coupled by shared electrostatic and magnetic lines of force. Impose an r-f signal on one coil and extract it from the second coil.

If a highly conductive sheet of significant size is put perpendicular to the axis of the coils, between them, and solidly grounded, most coupling, electric and magnetic, is eliminated.

Electric coupling is short-stopped and shunted to ground by electric lines of force striking the shield.

Magnetic coupling is short-stopped by induction of current in the shield which opposes the induction (Lenz`s law) and results in a null between the incident and reactive fields.

It is practical to allow magnetic coupling between the (transformer) coils while disallowing electrostatic coupling by using a special shield. In the broadcast transmitters I`ve worked with, the shield simply had many parallel slots cut at equal frequent intervals either from top to bottom or from side to side. The pickets formed from the slicing were firmly grounded at one end but not both. The shield made this way is called a Faraday screen.

Electrostatic lines of force from the adjacent coils sharing an axis terminate on the grounded pickets so that none can directly pass between the coils. So, there`s no capacitive coupling between the coils.

Since one end of the pickets is open-circuit, no induced current can circulate between them. Lenz`s opposing field can not be generated to nullify magnetic coupling between primary and secondary of the coupling transformer formed by the adjacent coils.

There are tens of thousands of examples in U.S. broadcast stations working perfectly at this very moment. You may be listening to a signal sieved through just such a strainer at this moment. I am.

Best regards, Richard Harrison, KB5WZI

Source record: 113797
Cross-posted to: alt.radio.amateur,fido7.hamradio,nl.radio.amateur,rec.radio,rec.radio.amateur.antenna

The one critical piece of missing information is the frequency or wavelength. Manipulating some equations from King, Mimno, and Wing's _Transmission Lines, Antennas, and Waveguides_, the field necessary to generate a particular power P in a load connected to a receiving antenna is

Erms = (1/WL) * sqrt((240*pi^2*P)/G)

where Erms is the RMS field in V/m, WL is the wavelength in meters, and G is a complex function calculated and graphed in the text. (It's f in the text; I used G to avoid confusion with frequency.) This is for an infinitely thin antenna parallel to the impinging field, terminated with the complex conjugate of its feepoint impedance. For a half wave dipole, G is about 0.82. But a half wave dipole has a gain of 1.64 relative to an antenna with 0 dBi gain. So a field sqrt(1.64) = 1.28 times greater would be required for the 0 dBi antenna. Plugging in the numbers,

Erms = 119.2/WL volts per meter.

It should be possible to confirm this with NEC-2 by modeling a terminated dipole with an applied plane wave source. (EZNEC doesn't have the capability to model the plane wave source.)

All three common formulations of antenna modeling software (MININEC, NEC, and MININEC Professional) agree quite closely that the resonant length of a square loop in free space is about 1030/f. I noticed this some time ago, and wondered about the discrepancy between it and the widely believed and repeated value of 1005/f. I got convinced by some folks who made careful measurements that the approximate 1030/f value is indeed correct, for bare wire. If a wire has normally thick plastic insulation, it'll need to be shortened by roughly 3%.

I'm guessing that the 1007/f value you got from EZNEC was that low because of proximity to ground -- if it was a free space value, please contact me, since I've always seen results around 1030/f for free space. Ground will have an effect, so modeling can probably get you closer than using a formula. But sag, stretch, and as Tam says, the difficulty in measuring the wire length accurately, will likely cause some disagreement between model and practice. So expect to do a little tweaking even if you model it first.

Uhhhhh Jim, you are the one who is implying that the energy flowing into
a lossless impedance discontinuity in a transmission line is NOT equal
to the energy flowing out of that impedance discontinuity. So who doesn't
understand the laws of nature? Can you prove your assertion?

> Energy is not necessarily conserved within any arbitrary boundary.
> Your notion of energy conservation is sophomoric.

Energy is necessarily *always* conserved, Jim. Please give us an example
where energy is not conserved.

>>If reflected waves transfer no energy, how does the reflected wave heat
>>up a resistor?
>
> Obviously the circulator load resistor heats up when energy IS reflected.

Just as obviously, the reflected wave must be smart enough to know, ahead of
time, whether to carry energy back from the mismatched load or not. How does
the wave get smart enough to know that, Jim. That wave is even smarter than
you since, from the load location, you cannot tell if a mismatched load is
located in a matched system (or not) by looking only at conditions existing
at the load.

You are located at a load outside the hamshack. You are a pretty bright fellow
and you want to tell the reflected wave whether to carry energy back to the
circulator load resistor or not. Unfortunately, neither you nor the reflected
wave have any way of knowing whether that circulator load resistor is in the
circuit or not. Why are your reflected waves smarter than you are? They have
to be able to sense the existence of that circulator resistor at faster than
light speeds to know whether to carry reflected energy or not.

Oh, I've learned from you all I care to know about quoting
equations out of context and ignoring embarrassing questions.
It is perfectly understandable that you refuse to answer
questions when you know the answers would prove you wrong.

Speaking of embarrassing questions: Your equation said that,
"Pi = Pf + Pr", which I assume means that

Pincident = Pforward + Preflected

So given an impedance discontinuity where s11 = RHO = 0.5,
What is the law of physics mechanism that allows Pr to
be zero when the physical impedance discontinuity possesses
a physical reflection coefficient of 0.5? Please be specific.

There are a good half-dozen embarrassing questions that you
have refused to answer. One wonders why?

It shouldn't be making much of a difference though. How will grounding
reduce the noise level? Ground is a noise source. It's actually better
not to be hooked to it in my opinion. Here, with my coax fed dipoles,
adding a shack ground makes no difference in noise on any bands,
except for a slight increase in signal strength on the low bands.
160m, MW, etc. If grounding your station reduces noise, I'd be
wondering how well your balun, choke, etc, is actually working.
I don't use a shack ground at all, and I don't have noise problems.
With a balanced dipole, and properly fed with a balun or choke if
using coax, there should be no reason at all to need a ground to
reduce noise. If it does help, in my opinion, you have an
antenna/feedline decoupling problem. MK

I also live near a volcano. The ground is lava ash - not hard, but very
poor moisture retention, and lousy ground conductivity, except when wet.
Radio reception is not particularly good here, even with the elevation.

The only way to ground effectively here is a ground plane radial network.
It also helps to keep the ground wet around it.

Roy,

I think my antenna is not a good example, because it is not square, but rather 80 x60.5 x 65 x 60.5 . I looked at the EZNEC file, and it was modeled with the bottom (80ft) wire at 15 feet, top (65ft) wire at 70. Trees don't always grow where you want them to. Note that the length is 266, not 265 as I thought.

You seem to be agreeing with Cecil that insulation will lower resonance. Does the insulation make any difference if the wire is in free space?

Pete wrote:
"You can (have) a good ground for lightning that will heat earthworms with RF."

I`ve tried to think how?

A good lightning ground bypasses earth capacitance with low resistance. A good lightning ground must have low reactance in addition to low resistance. Lots of ground radials make a good radio ground. They also make a great lightning ground. A lone ground rod makes a lousy radio ground. It also makes a lousy lightning ground.

Much of a lightning stroke`s energy is in its abrupt start and stop. That`s why it generates a wide r-f spectrum. Heard any radio static lately?
A large inductance may vitiate an r-f ground. It will just as surely vitiate a lightning ground with the difference that it can`t be tuned out of the lightning ground.

Uncle Peter may be mistaken.

Best regards, Richard Harrison, KB5WZI

"Energy" is *NEVER* reflected! current is reflected, electrons are what is
moving not 'energy'. power is calculated from current, and energy is
integrated from power... at each step of going from current to power to
energy you lose vital information about what is happening at the physical
level, no wonder it is so confusing.

> 73, Cecil http://www.qsl.net/w5dxp
[snip]

Heh, heh... come on Cecil, you can't have it both ways!

Standing waves only "stand" because" of a steady state condition.

To "stand" things must first be "steady".

During the transient [build up] period when incident waves and their echos
are
sloshing back and forth "longitudinally" along the line bouncing off the
impedance
discontinuities and such there are no "standing" waves, only "travelling
waves".

After the line has become fully charged and for all practical purposes has
reached
the final "steady state" the energy "stored" on/in the line is then sloshing
from side to
side "transversally"alternatng between the distributed line capacitance
[electric field]
and distributed inductance [magnetic field] there is an observable steady
state standing
wave which is a manifestation of that transversal vibration of energy and
which stores
that energy on the line.

What's more, during the steady state regime, that stored energy in the standing wave
ain't goin nowhere [that's why it's called "standing"] until the prime mover excitation is
removed from the line and the line is allowed to discharge!

It just makes no sense to carry transient terminology and analysis through into a
steady state analysis because even though all the equations are still mathematically
correct they do not describe the physics of that steady state regime.

> there is only one value for RHO^2, the power reflection coefficient.

From pg. 63, Born and Wolf:

For normal incidence, cos theta = -1, and n1=1 (Z0=50), then r12 and r23 are given by r12=n1-n2/n1+n2, r23=n2-n3/n2+n3, and reflectivity R = ((r12-r23)/(1-(r12*r23)))^2 = (((n1*n3) - n2^2)/((n1*n3)+n2^2))^2. "The reflectivity is then a maximum or a minimum according to whether the refractive index [~impedance] of the film [n2=1.22, ~Z1=150] is greater or smaller than the refective index of the last medium [n3=1.5, ~ZL=450]."
In the reflected direction the indices are in the reverse order.

In other words R for the matching network is a minimum in the transmitted direction and a maximum in the reflected direction. Pretty much exactly what Walter Maxwell has said. In other words, no energy is reflected back toward the source from the first boundary, and any energy reflected by the load is 100% re-reflected by the back side of the second boundary.

But Cecil will claim this is only a steady state analysis and is therefore......irrelevant? The seductive part is the accuracy I suppose.
The point is that any detailed energy analysis of what goes on within the boundaries must be completely consistant with the steady state analysis. The steady state analysis precludes energy reflected from the load from passing back through the second boundary.

That simply illustrates the difference between standing waves and
stationary waves. Standing waves aren't necessarily stationary.

Insulation does lower resonance. So to bring resonance back to where you want it, or where EZNEC predicts, you have to shorten the antenna slightly compared to the model. Yes, insulation does make a difference even when the antenna is in free space. The effect is essentially independent of the environment.

Your paper describes a device which does that. Waves superposition?
Pref=P3+P4-2*sqrt(P3*P4)? Is that specific enough for you?

After years of getting my coax whacked with the lawnmower, I'm going to bury it. I plan on burying some PVC water pipe and pulling the cable through. I'd appreciate any suggestions about how to make the installation trouble free. I can keep rain out with some U fittings at the ends. But am I likely to have water accumulate from condensation? If so, what's the best way to deal with it -- particularly considering that the ground here is completely saturated with water for about half the year? Can I just make sure the coax is in good condition and ignore water in the pipe? Any other suggestions?

I'll initially be running one piece of RG-213 and a multi-conductor control cable for a remote relay box, but want to leave room for a few other cables in the future.

Thanks!

A lousy, 100-ft line tied to a rusted shallow rod, maybe, because it
resonates, but a proper (short, low-impedance) ground can never generate
noise.

> It's actually better
> not to be hooked to it in my opinion. Here, with my coax fed dipoles,

> wondering how well your balun, choke, etc, is actually working.

Baluns and chokes have nothing to do with it (although most of my PC's
cables have dozens of snap-on chokes, btw). It is all the noise
generating devices present within the shack that need their grounds tied
together to a single point ground rod and then off to a good ground
outside. All these digital devices with SW range clocks create plenty of
harmonics and loop currents through the various cabling around the
receiver.

> I don't use a shack ground at all, and I don't have noise problems.

Well, here's what's grounded in my shack besides my rig and amp:

PC, radio i/f, electronic keyer, 12V supply

And here's more noise causing equipment that cannot be grounded directly
(but actually is by grounding the PC):

scanner, Laserjet, cable modem, router, laptop with cradle

My shack is not an ideal situation, mind you, since the antenna is
fairly close to the house, but then again, that is more of a rule than
an exception for most hams.

> With a balanced dipole, and properly fed with a balun or choke if
> using coax, there should be no reason at all to need a ground to

> antenna/feedline decoupling problem. MK

Probably, although that should not make a difference for receiving. All I know is, grounding has always been good for me. Especially a single point ground in the shack.

The factors are permittivity (dielectric constant), conductivity, and frequency. Styrofoam has a negligible loss up to several GHz at least, probably tens of GHz.

Note that if the styrofoam is very close to or in contact with the antenna, it might cause slight detuning because of its dielectric constant.

Leave the pipe, just burried them as they are, if you can lay bricks
on top to prevent digging in them. I have cabels that have been in
the ground for over 15 years and they looks better than them on
my mast.

Regards Max

From what I've read in other forums, there is no way to prevent
moisture from entering the pipe one way or another, so use a
non-corrugated conduit and try to slope it either toward the house, the
tower or both. When I get around to doing this, I'll bury a 4" diameter
pipe, then I'll run the coax in a 1" conduit and the control cables in
another 1" conduit and then pull the whole thing through the 4" pipe.
Then seal the 4" pipe to stop bugs and rodents.

> I'll initially be running one piece of RG-213 and a multi-conductor

Wouldn't you be better off with LMR-400? Only slightly more expensive
and almost 50% less attenuation than the RG-213? You can even get
LMR-600 (65% less attenuation) for less than $1/ft if you shop carefully.

Hi Roy,
Without pressurizing I don't think we can keep condensation out. I leave the ends open to breathe (but pointed down so rain cannot enter). Many years of LMR400 in the ground and the loss to my 1296 MHz EME dish shows attenuation to be the same as day of installation.

> moving not 'energy'.

The wave energy is moving at the speed light. Electrons cannot move at
the speed of light.

It is impossible to reflect only the current part of a wave. There's always
a voltage component involved in the reflection. The power in the reflection
is |V*I| in joules/sec. Those joules represent energy in the reflected wave
E-field and H-field.

One more example of seduction by the steady-state model. "No such thing as
reflected power."" No such thing as reflected energy.""No such thing as
reflections."

That's exactly the problem. That's why the QEX article says
75W + 8.33W = 133.33W, assuming that the powers represent
the voltage vector quantities. That's one of my objections.
75W + 8.33W does NOT equal 133.33W under any circumstances.

Source record: 113729

Roy,
Just a suggestion or two. Use a pipe larger than you
think you will need, cuz you'll always wish you had room
for just one more cable run. If the pipe comes out inside
your house, be sure to stuff it with something to keep the
'critters' out! Using two 45 degree 'elbows' is better than
using one 90 degree 'elbow', when you start pulling cables,
makes it lots easier. Also, don't glue the last elbow (or
two) at the tower, just another thing that makes running
cables easier.
From the sound of it, your pipe is going to have moisture
or water in it no matter what you do. Depending on how
'fancy' you want to get, keeping air moving through it from the
indie toward the tower can help. Other wise, just be sure not
to have any joints/connections inside the pipe.
Oh, make a 'loop' of fairly heavy cord to drag the cables
through the pipe and never remove it! (Sort of like the
'clothes
lines' on a pully?) Remember to replace it every year or so.
Much easier than trying to push a rope...
'Doc

Roy,

I used PVC pipe to protect the coax going to my vertical. Condensation will not be a problem, it can't accumulate enough to cause bursting of the pipe and most quality coax of the direct burial type will further protect against it. Worked out for over 10 years for me.

73s,

Evan

Instead of using plumbing pipe use Electrical conduit.
You can get sweep 90 degree bend for that and also what is called a
weatherhead to bring the cable out.
The top is removeable for future cables.

About a week ago I asked if anyone recognized a certain antenna......It was a three element vertical......With each element 120° apart....Several of you said it sounds like an old CB Super Scanner........And you were right....This antenna fascinates me as it is a beam with no rotor......It has a control box in the shack and a relay at the mast......In one position you make a radiator and the other two elements become reflectors and so forth in the other two directions......When you select all three elements the antenna becomes an Omni....Being a newbie I find this incredible.....Anyone have any experience with this antenna? good or bad........Anyone know if this antenna is available anywhere? Thanks Jack D.

>>incident wave? Please be specific.
>
> Your paper describes a device which does that. Waves superposition?
> Pref=P3+P4-2*sqrt(P3*P4)? Is that specific enough for you?

P3 is the power in one of the rearward-traveling reflected waves
that you say isn't there.

P4 in the power in the other rearward-traveling reflected wave
that you say isn't there.

2*sqrt(P3*P4) is the destructive interference term that feeds the
constructive interference on the other side of the impedance
discontinuity which you say isn't there.

P3 = |s11*a1|^2 = Pfwd1*RHO^2 power associated with wave, s11*a1

P4 = |s12*a2|^2 = Pref2(1-RHO^2) power associated with wave, s12*a2

s11*a1 and s12*a2 engage in wave cancellation (destruction) such
that b1 = s11*a1 + s12*a2 = zero.

P stands for "power" and you say those two rearward-traveling
reflected waves don't possess any power.

So you need to invent another mechanism. That one proves virtually
everything you have said is wrong.

I've had 6 runs of 9913 buried in a 4" PVC pipe for 16 years without
any problem, about a 75 foot run. It's about two feet down and rests
on a gravel bed. At the tower end, I have an inverted "U"
weatherhead. At the house end, the pipe runs through the concrete wall
in the walk-out basement through two 90 degree bends, sort of a
reversed "Z". Otherwise, no special considerations for condensation.
I'm in Virgnia, near Washington DC and we get plenty of rain and it's
cold enough in the winter to freeze. I periodically check the
feedline for loss and haven't seen any problems.

Of course, leave a messenger rope in place should you wish to run
additional feedlines.

For economic reasons plastic sheaths of underground phone cables replaced lead sheaths many many years ago without ingress of moisture. At least they did in the old British Post Office in the 1950's. (There was a small increase in noise induced from adjacent services such as railways and tramways.)

Phone cables are drawn into earthenware ducts only to provide mechanical protection and to allow easy replacement by different cable types when necessary. Ducts regularly contain running rain water without any effect on cable insulation which is maintained at many thousands of megohms per mile per wire.

Cables are often kept at a constant elevated dry air pressure by pumps at the terminal stations. This serves two purposes - if the duct and cable is damaged by workmen working on on adjacent services, such as water or electricity supplies, water is kept out of the cables and they carry on working normally until a repair can be organised several days later if necessary.

Also at intervals of a few hundred feet, a pressure operated switch is connected across a spare telephone pair of wires in the cable. If a hole should occur in the plastic sheath then pressure falls in the near vicinity and the reduced internal air pressure allows the nearest switch to place a short-circuit across the cable pair. An alarm is sounded at the terminal station, the time is recorded, and the repair man is called out of bed or wherever he may be.

The resistance of the short-circuited pair is measured and the distance in yards to the short-circuit is accurately determined.

Air diffuses fairly slowly along the cable. The first short-circuit to occur is the one nearest to the cable leak. The next short circuit occurs some time later on the other side of the leak. By juggling with resistance measurements and time, the location of the cable damage can be sufficiently accurately located. But phone traffic continues without interruption - air pressure keeping water at bay.

Having said all that, the fastest way of finding where the damage is is to drive along the route and look for somebody digging holes. If you can catch them in the act you may be able to obtain payment for the damage.

Many deep water submarine cables are plasic-sheathed - water pressure is tons per square inch. There's one peculiar effect - water disassociates under high pressure and pure hydrogen diffuses into polyethylene. If there are air spaces in a cable after a number of years high pressure hydrogen accumulates. Soon after ww2 a German undersea coax cable was being repaired

by a British cable-repair ship. It was picked up from the sea bottom and an undamaged length was laid across the deck. The coax insulation was partly air-spaced. The cable jointer had a blow-lamp roaring away. The jointer sawed into the cable and suddenly there was a great flare of burning hydrogen. He was not severely burned. He thought he had cut into a north sea gas main before oil had been discovered there. That's how diffusion of hydrogen through polyethylene was discovered. No Ph.D was awarded.

Why not check with cable manufacturers how fast ordinary water percolates through ordinary pvc buried directly in your wet back yard? There may be special grades. How long do you want the stuff to last anyway ?

who said electrons were trying to move at the speed of light? i said
electrons are moving, i didn't say how fast... the point is that its the
electrons moving that we call current, that is the basic element and proper
starting point for discussing this stuff.

> It is impossible to reflect only the current part of a wave. There's

> is |V*I| in joules/sec. Those joules represent energy in the reflected
wave
> E-field and H-field.

ah, but you only need to analyze EITHER the voltage OR the current, either
one is sufficient to completely specify a solution. Power or energy
computations are not sufficient to solve transmission line problems. As i
have said before, you start with current or voltage, you compute power from
that and lose phase information in the process, then you integrate power
over time to get energy, throwing away more information in the process...
then you can conserve energy, if you include the whole system with all
sources and sinks. remember the old refrigerator problem.

>
> One more example of seduction by the steady-state model. "No such thing as
> reflected power."" No such thing as reflected energy.""No such thing as
> reflections."

ah yes, the rant against the sinusoidal steady state case assumptions, this just goes to show how little you really understand of circuit analysis. you keep ranting against this because you don't understand the proper way to use it, if you did you would understand why power analysis is neither necessary nor very useful... I'll bet you even like to try to analyze complex matching problems with swr meter readings.

What do you mean when you say the squelch clears up? With the squelch,
the sound should be muted when there is not enough signal to break it,
but stronger signals should break the squealch easily. Is there a knob
to adjust the level of the squelch?

I don't think this has anything to do with grounding, or the lack of
one, especially if you are just receiving and not transmitting.

Why don't you read a physics book, just like the rest of us.

> > Energy is not necessarily conserved within any arbitrary boundary.
> > Your notion of energy conservation is sophomoric.

> Energy is necessarily *always* conserved, Jim.

Read all of the words to yourself out loud, Cecil. Energy is not
necessarily conserved in an open system. When you draw a boundary in
such a way that the system within it is open, energy probably will not
be conserved within the boundary. Really basic stuff. Your network is
an open system that happens to be an example in which energy is
conserved within the boundary around it. But your equation describing
the equality between influx and outflux is NOT the Law of Conservation
of Energy. It is simply consistant with conservation of energy.

> Please give us an example
> where energy is not conserved.

Draw a boundary around a power plant, and see if you can prove that
energy within that boundary is conserved. (I thought I already gave
that example.)

> light speeds to know whether to carry reflected energy or not.

Here's a simply way for you to understand this. (Requisite: simple.) Does the wave have any place that it can go? If yes, then it has a place to which it can transfer energy. If no, then it doesn't have a place to which it can transfer energy. When you put a circulator in circuit you are doing two things: one, you're eliminating the wave cancellation; and two you're providing a place to which energy can be transferred.

Sure. "Transmission Lines and Networks", Walter C. Johnson, page 150,
equation (6.17).

"P = |E+|^2/Z0 - |E-|^2/Z0 We can regard the first term in this
expression as the power associated with the forward-traveling wave,
and the second term as the reflected power" (associated with the
rearward-traveling wave). Note E+ and E- are RMS values.

In other words, if a transmission line wave possesses a voltage, it
also possesses a power, V^2/Z0 or I^2*Z0 or |V*I| or ExH.

Because you mentally violate it willy-nilly. Here's a quote that
proves your "region of space" assertions wrong. From "Fundamentals
of Electric Waves", Skilling, 2nd edition, page 131.

"Consider a region of space, enclosed within an imaginary surface."

This is exactly what I did with the transmission line impedance
discontinuity point which you implied was an invalid thing to do.

"The rate at which EM energy flows out of this region is found by
integrating P over the enclosing surface. ... But, if the energy
is flowing out of the region, there must be a corresponding loss
of EM energy stored within the region." The same thing is obviously
true for energy flowing into the region. Thus, contrary to your
assertions, Pfwd1 + Pref2 = Pfwd2 + Pref1, is a statement of the
Conservation of Energy principle.

It is you who wants to ignore the energy in the two reflected waves, Jim,
not I. I am basing my entire argument upon those other reflective surfaces
and the reflected waves generated by them. Nice try at obfuscation.
Didn't work.

a line can have a voltage but not 'possess' any power, or be transmitting
any power.... but it could still have energy... I'll leave the derivation as
an exercise for the student.

Never tried to push a rope....

Tie a lightweight cord to a wadded up kleenex or two and suck
it through the pipe with a shop vac. Then use that cord to
pull a heavier cord (or the cable) back through the pipe.

Absolutely false. How do you explain TV ghosting and measurable standing
waves occurring at the same time?

> After the line has become fully charged and for all practical purposes has reached
> the final "steady state" the energy "stored" on/in the line is then sloshing from side to
> side ...

Please describe how standing waves are even possible in a single source,
single feedline, single load system without a forward-traveling wave and
a rearward-traveling wave. This is a very large hole in your argument.
The two traveling-wave components are the *cause* of the standing wave and
do not cease to exist merely because you superpose them in your head.
(Unless you are God, and in that case, I apologize. :-)

> It just makes no sense to carry transient terminology and analysis through
> into a steady state analysis because even though all the equations are still
> mathematically correct they do not describe the physics of that steady state regime.

On the contrary, they describe it exactly. That's why you guys are afraid of it.

Mentally hitch a ride on a forward source wave in a matched system with reflections.
You are approaching the physical impedance discontinuity point. What is the first
thing you encounter? - not waves, the first thing you encounter is the physical
impedance discontinuity with its reflection coefficient, e.g. 0.5. Why doesn't the
forward wave react to the physical impedance discontinuity? answer: it does and that's
why the s-parameter equations work perfectly. s11 is really there, a1 is really there,
s12 is really there, a2 is really there. The forward wave doesn't see any reflected
waves because s11*a1 engages in wave cancellation with s12*a2. Those wave components
actually exist, at least for a dt of time in the case of s11*a1. Mother Nature is
actually superposing those four s-parameter wave components.

You have been seduced by the steady-state math model and you enjoyed it.

Michael Hart wrote:
"---design of a HF traveling wave broadband HF dipole made from coaxial cable."

You have been well directed to Cebik`s pages. Cebik is a treasure and I won`t touch the coax bazooka stuff.

Michael has been introduced to a broadband folded dipole with a load resistor opposite its feedpoint. It has much to commend it for certain applications. It is inefficient for others. Barker&Williamson make commercial versions and have a loyal group of customers.

A traveling wave antenna is intended to be less periodic or resonant than a standing wave antenna such as a dipole. It is usually long in terms of wavelengths and is terminated in its characteristic impedance so as to not make waves.

One of the oldest traveling wave antennas is the horizontal rhombic. A transmission line is fairly independent of frequency but it is a poor radiator because its parallel wires are balanced and close together. The rhombic idea was to gradually widen the space between the wires so as to not make waves but to induce radiation by wide spacing.

The wires could then be brought together again just as they had been separated to restore the original line impedance.

The divergent / convergent wires could be raised to a height as needed for low-angle radiation.

The angles of the diamond-section antenna could be optimized for best alignment of radiation from its four sides.

Finally, the far end of the diamond antenna / transmission line could be terminated in its characteristic impedance, usually a dummy load, to avoid a reflection which would produce radiation back toward the sending end of the antenna.

The rhombic works best when its sides are each several wavelengths (often 3,4 or 5) long. Its gain is high and usually most energy is radiated before reaching the sink which is its termination.

The loaded, folded dipole isn`t so fortunate. It has neither the gain nor the efficiency of the rhombic, but it does take a lot less space and hardware.

Best regards, Richard Harrison, KB5WZI

If you were to solve the equation, you would certainly see that no
energy is conveyed as a result of its interaction with P4.

> P4 in the power in the other rearward-traveling reflected wave
> that you say isn't there.

Also conveys no energy, as a result of its interaction with P3.

> 2*sqrt(P3*P4) is the destructive interference term that feeds the
> constructive interference on the other side of the impedance
> discontinuity which you say isn't there.

The interference term "feeds" nothing. It is simply part of an
expression for either the forward or the reverse power. In this example
it gives the reverse power. P1 and P2 can be used to calculate the
forward power.

But it's true that the wave reflection model would instead (and more
appropriately) use the voltage expression, Vfwd^2 = V1^2 + V2^2 +
2*(V1*V2) to calculate the resultant forward voltage. That result would
then be divided by the impedance in order to calculate the forward
power. As we know from the first paragraph in any treatment on
interference, powers and intensities don't simply add.

> P3 = |s11*a1|^2 = Pfwd1*RHO^2 power associated with wave, s11*a1
>
> P4 = |s12*a2|^2 = Pref2(1-RHO^2) power associated with wave, s12*a2

P3 and P4 are really only mathematical constructs since V3 and V4
cancel. But since P3 and P4 effectively do the same thing, there really
is no difference in the outcome.

> s11*a1 and s12*a2 engage in wave cancellation (destruction) such

> P stands for "power" and you say those two rearward-traveling
> reflected waves don't possess any power.

How much power does b1 represent? I still have never said anything about waves having possessions. I deliberately try to refrain from using anthropomorphic terms.

TV signals can almost never be considered to be in steady state so would not satisfy the requirements to use that method. this has been explained to you before. real world meters will average the transients so that you can read forward and reflected power, but if you study them in detail there is no steady state.

> greater or smaller than the refective index of the last medium [n3=1.5,
> ~ZL=450]." In the reflected direction the indices are in the reverse order.

Those are light reflection indices which are not the same as transmission line power reflection coefficients. They are equivalent to the voltage reflection coefficients in a transmission line and indeed, for voltage reflection coefficients, the signs are different looking in opposite directions. But that is not true for power reflection coefficients which depend upon RHO^2. Every RHO^2 is positive. The same percentage of power is reflected in both directions at an impedance discontinuity in a transmission line so your point is irrelevant.

> In other words R for the matching network is a minimum in the
> transmitted direction and a maximum in the reflected direction. Pretty
> much exactly what Walter Maxwell has said.

Your Rmaximum and Rminimum at any one plane have the same magnitude and opposite signs. Walter Maxwell said nothing remotely resembling that. He said the reflection coefficient for the forward wave is zero and the reflection coefficient for the reflected wave is unity. Those are calculated mathematical reflection coefficients, not physical reflection coefficients.

> In other words, no energy is
> reflected back toward the source from the first boundary, and any energy
> reflected by the load is 100% re-reflected by the back side of the
> second boundary.

You are bending the truth to the breaking point. R for forward and reverse directions are equal in magnitude and opposite in sign. One is NOT zero and the other is NOT unity.

> The point is that any detailed energy analysis of what goes on within
> the boundaries must be completely consistant with the steady state
> analysis.

There's that old "math model dictates reality" mentality again, Jim. The exact opposite should be true. The steady-state analysis is supposed to agree with reality, not vice versa. The steady-state analysis is a short-cut method that represents reality on the macro level but not at the micro level.

For instance: Standing waves are impossible in a single source, single feedline, single load system unless a forward traveling wave exists and a rearward traveling wave exists. Once the standing waves are calculated, you guys forget or deliberately ignore the existence of the cause of the standing waves. That may give you the correct macro answer to your problems, but it certainly confuses you about what is actually happening in reality.

You guys need to attend a chapter of "Steady-Staters Anonymous" and rid yourselves of your addictions. Until you do that, you will never be able to face reality like a man.

They could be peak values if you include the rest of the wave equation
for each term. But as we know, power doesn't actually flow in a
transmission line, and no energy flows when E+ equals E- because the
resulting electric field is zero. By the way, the equation doesn't
express what you said it does.

> > In other words, if a transmission line wave possesses a voltage, it

Absolutely true. Cecil has a problem with the fact that a transmission
line can have EM energy stored within it without there necessarily being
a continuous transfer of EM energy somewhere. Understandable though,
being that the idea is counterintuitive to some extent.

Hi Roy,

If you are going to use pipe, I would use the gray electrical conduit.
One reason, as another poster mentioned, you can get the long sweeps
for the corners. Even with those it is very difficult to pull cables
through if you make a few bends. Second, the gray pipe noted for
electrical wires will be less likely to be cut by someone installing
phone lines, sprinklers etc. They will think it contains electrical
wires and will leave it alone.

If planning on pulling more wires latter, use a VERY large pipe unless
you will have no corners in it.

I have a run of about 120 feet that goes under the drive way and
around the back of the house. I put in 3 runs of 7/8 hard line
directly buried. I also have some 2" (or 2 1/2") conduit with 2 or 3
runs of RG8 and several runs of multiconductor control cables.

I did run a nylon cord for future cable pulling but it is so difficult
to pull that I know I will never be able to pull anything else
through.

When I put the cables in I ran them through the pipe before I glued
the pipe joints. Good thing too as I would have never been able to get
them through all the bends. Even though I have the long sweeps on all.
I had to open most of the bends to pull the cables around at that
point.

To terminate the lines I mounted a large plastic "J" box (available
from electrical supply houses) on the wall and brought the conduit up
into it. I also come back out the bottom of the box with the jumpers
to go inside the house. Same at the tower end. The boxes provide a
nice water proof junction for connectors and to attach grounds,
lightning protectors etc. to the cables. Also makes for easy changes
while keeping everything dry.

I have about 100 feet of 6 in dia plastic pipe thru which are about 6
coax lines and a few control multi wires. I did not secure the pipes,
just pushed them into each other. After a few years some mud got into
it but not to a point that I had to do anything about it(frost
heaving perhaps). I have 3/8 stiff (not flexible) steel cable that is
left inside for pulling e.t.c. If I had to do it all again I think I
would use two plastic tubes so that control wires were in a separate
pipe on top of the other pipe.Rather have water in the coax tubing and
let it provide drainage around the control wires pipe.Inlet and exit
are angled to the surface to make pulling easier.
One time I had a dozen wires thru the pipe and one of them tangled
with a coax,
not a big deal but it did happen. My pipe has been in the ground for
about 20 years and it is always nice to have the extra coax available
for comparison purposes.

Power or energy computations are sufficient to solve for any voltage, current, or power around an impedance discontinuity match point. Did you realize that? All voltages and currents are either at zero degrees reference or at 180 degrees.

> I'll bet you even like to try to analyze complex matching
> problems with swr meter readings.

It works pretty well. The only thing I can't calculate is the sign of the reactance. Adding a cap and noting which way the meter moves tells me the sign of the reactance. How do you think the great minds of 200 years ago managed to come up with what they did without $20,000 network analyzers? Not only are you guys seduced by the steady-state model, you are also spoiled by modern technology. :-)

>water in the pipe? Any other suggestions?

I have no experience with buried coax... only with buried comm
cable.

The trick is usually to put gravel in the trench below the
cable, supposedly to drain water away from the conduit. But
obviously if you have standing water higher than the level of
the conduit, it is not going to drain. You probably don't want
splices in such an area if it can be helped, and you do want to
do a very good job of making waterproof junctions when
necessary. (Steel conduit is commonly used, rather than PVC,
because it can be sealed better and is less fragile, but that
might be going a bit farther than you'd want.)

Condensation should not be a problem. Typically you want the
ends sealed in a way that allows air, but wards off moisture and
things that crawl. A U filled with foam material at the end and
a rubber cap with a hole just large enough for the coax to exit
is typically used here.

Under no circumstance to you want water to enter the conduit!
I'm not sure where you live, but if it were to freeze the
pressure could destroy your coax.

>I'll initially be running one piece of RG-213 and a multi-conductor
>control cable for a remote relay box, but want to leave room for a few
>other cables in the future.

Install the conduit. Then use a foam ball with a string
attached to blow (using compressed air) a string through the
conduit. The string is used to pull a 1/4" poly rope through.
Have another length of rope, and any time you pull a wire, pull
a rope along with it. That way you always have a pull rope for
the next time. Pulling 200-300 feet of 3/4" comm cable through
a 4" conduit is actually very easy (particularly if you stand
there and watch a couple young fellows do it!).

More bafflegab. I solved the equation P3=V3*I3=25W. P3 contains
25 joules/sec. P4 contains 25 joules/sec. Those joules/sec cannot
be destroyed except in your mind.

>>P4 in the power in the other rearward-traveling reflected wave

It certainly conveys energy from the destructive interference event to
the constructive interference event just as described on the Melles-
Griot web page.

> The interference term "feeds" nothing.

So you disagree with _Optics_, by Hecht. Why don't you take it up
with him? Hecht says the destructive interference event feeds energy
to the constructive interference event.

> P3 and P4 are really only mathematical constructs since V3 and V4

Sorry, Jim, the intrinsic energy in a wave cannot and does not cancel
when the voltages and currents cancel. That is what you are missing.
You are mentally violating the Conservation of Energy principle.

If we filter out some coherent light from Alpha Centauri, create two
equal magnitude, out of phase waves, and cause them to cancel to zero,
are you saying that light from Alpha Centauri never contained any
energy. Preposterous!

Dear Roy:
Let me come at this from a different direction and with a different experience.
I have several 400+ foot runs of Heliax that are just on the ground plus some control cables. Never a problem. One of the runs is about 30 years old and it was measured a couple of years ago to be within original specifications.
One secret is to use Heliax. One receives what one pays for. Use proper connectors.
The other secret is to use a mower. One needs to use a mower that has a floating cutting head that stays 3 inches above the ground. My guess is that you are using too aggressive a cut (too short) with a head that is able to be other than parallel to the ground.
Lowest cost engineering solution: Use Heliax. Get, and use, a real mower.

We do not have quite the rain fall that you have, however things stay green. Leave the grass a bit taller. Save yourself a lot of work.

> that example.)

Exactly what energy is created or destroyed in a power plant?

>
>>>Obviously the circulator load resistor heats up when energy IS reflected.
>>
>>Just as obviously, the reflected wave must be smart enough to know, ahead of
>>time, whether to carry energy back from the mismatched load or not.
>
> Ahead of what time? I don't understand your dilema here.

That's obvious. The wave is in the act of being reflected from the load. It
doesn't know what to expect at the source end of the line when it arrives
there. It might have to dissipate power and it might not have to. But that
is 100 nanoseconds into the future. You say the reflected wave carries energy
if energy is needed but the wave doesn't know if it will be needed or not
in 100 nanoseconds. The reflected wave must predict the future. If energy is
needed to heat a resistor, it must take energy with it. If energy is not needed,
you say it doesn't take any energy with it. So how does it predict the future,

Jim, when you, with your high IQ, are incapable of predicting the future? Your scenario has a large contradiction built in. It not only requires smart waves, it requires waves smarter than you, smart enough to predict the future.

> When you put a circulator in
> circuit you are doing two things: one, you're eliminating the wave
> cancellation; and two you're providing a place to which energy can be
> transferred.

The wave contains energy either way, Jim, because it cannot know what will happen in the future at the source. For one case, the wave delivers its energy to a circulator load. For the other case, the wave delivers its energy to the destructive interference event. Both ways, the energy is delivered. (Just as explained on the Melles-Griot web page and in _Optics_ by Hecht.)

"I`m debating whether to transmit from inside an enclosure that is primarily styrofoam---."

Fog, mist, and light rain have almost undetectable effect on propagation below about 10 GHz. Microwave fades are caused by stratified air in stagnant conditions which produce fog, not by the fog itself.

Dishes use plastic radomes with almost unmeasurable effect. But, plastics are lossier than air. That`s why spiral-lines and foam-lines, and other configurations to minimize plastic insulation are used.

Sure, losses can be contrived and some practitioners can fall on hard times without really trying, but with a little bit of luck, it won`t be you.

Best regards, Richard Harrison, KB5WZI

Of course, I am talking about RF voltage in a transmission line that is an appreciable percentage of a wavelength. A 1WL transmission line cannot have an RF voltage devoid of energy content. Every wave requires energy. Waves devoid of energy are not possible. Even the energy in a super-conducting transmission line wave is still there and can burn your fingers if the power is high enough and you grab it. Real waves devoid of any energy content are just supernatural wet dreams that apparently occur during the steady-state seduction process.

I forgot to mention something that is extremely important. *Mark*
the path of that conduit very well.

The 200-300 foot pull I mentioned was because the last comm
cable I helped install wasn't marked well, and 2 years later the
power company wanted to put in a pole. I showed 'em where I
thought it was (*they* had dug the trench, and didn't know!) and
said I wouldn't drill within 25 feet of that. So I was wrong.
They drilled 15 feet away and hit it dead center...

We got to pull another cable through...

> resulting electric field is zero.

The electric field is zero only at one infinitesimal point, Jim. On each side of that point, the electric field is alive and well. 1/4WL away from that point, the electric field is at its MAXIMUM value. That electric field cannot exist without a forward traveling wave and a rearward traveling wave each of which contains energy.

What you are saying is that no energy is flowing when two light waves engage in destructive interference and a dark ring results. Does you boss know you make stupid assertions like that one? Come on, Jim. You know that normal interference has absolutely no effect on energy flow. The two waves don't even know the other wave exists.

> By the way, the equation doesn't express what you said it does.

But we can assume it expresses what Johnson says it does and he disagrees with you. :-)

> Cecil has a problem with the fact that a transmission
> line can have EM energy stored within it without there necessarily being
> a continuous transfer of EM energy somewhere.

You can prove your point by offering an example of a single source, single feedline, single load system that has standing waves without reflected waves. Your response to that challenge has, so far, been nonexistent. When are you going to provide any proof of your assertions?

125. Carolina Cyclone Antennas (screwdriver)

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-02 02:34:33 UTC
From: Jerry Oxendine <joxendi@bellsouth.net>
Message-ID: <PwrMa.2167$eW6.1163@fe03.atl2.webusenet.com>
Source record: 113768

For those looking for a well-built, great-operating mobile HF antenna,
please consider the Carolina
Cyclone I and II antennas. I can also save you some money as well. Don't
worry about using power on these antennas, go ahead as per the website--800
watts and 1500 watts respectively.
Even the coil covers are heavy duty. Instead of the flimsy butyl covers that
come with *some*
screwdrivers, mine are 1/8" wall Lexan. And I will include the IC 706
tuning module for FREE.
So please visit http://www.qsl.net/k4kwh

Also you can type into google, "Carolina Cyclone" for a review or on Eham.

> steady state.

My point exactly, David. Given the noise that exists in every real system, steady-state *NEVER* exists. However, standing waves *DO* exist even if steady-state never exists. And you can track the noise all the way up and down the transmission line if you really want to.

> he's got you there... you can always use the complete solution, it is just

Point is, one cannot afford to forget the complete solution if one really wants to know what is happening in reality. The steady-state math model does NOT dictate reality no matter how strong you guys truly believe in your heart of hearts that it does. Noise transients continue to occur even during "steady-state" and they do NOT obey the steady-state shortcut rules.

Have you "busted" your screwdriver coil cover? Is it cracked or broken, and you can't find a replacement? Then visit www.qsl.net/k4kwh and you will find coil covers of several sizes and types. I have to provide these anyway for my Carolina Cyclone antennas, so it is a natural off-shoot as I have the material in stock.

What are you expecting to happen? what you get, is an animation
representing the current direction, and magnitude, on the antenna, you
sometimes have to look really close to see it if you have the radiation
pattern showing, as it's a lot smaller than the rp scale.

I would forget the pipe for enclosing the coax and use Heliax instead
of the '213. Since you're never going to keep water out of your
conduit, why not just use perforated drainage pipe and not worry about
it. This will also force you to use 4" pipe which makes pulling
future cable much easier. Your conduit will never be big enough :)

Agreed! If you use anything less than 4 inch you'll regret it. Two inch is virtually impossible to work with for any distance.
One professional installation I'm familiar with used a pair of two inch conduits in the initial construction, and the installers had to use a small tractor to complete the original cable pull. Several years later when I drew the job of making some upgrades we installed a pair of four inch schedule 40 PVC tubes, and now there's still room for future EASY upgrades.

The only settings I change is to select 'animate', and then I zoom way
way in so the j-pole fills the screen. Nothing moves. When I select
'current', I get pretty colors but they don't move.

If you've lost patience with me, that's totally okay. I understand.
If you're still motivated enough to try again to help me, I'd
appreciate it. It might help to give me a click-by-click set of
instructions. (you run the command 'xnecview animate.*' and you get
two windows. select the window with the antenna in it. Change the
top button from 'none' to 'animate', etc.)

Again, if I've only succeeded in demonstrating my incompetence with
the program, then I'll understand if you want to throw your hands in
the air and surrender.

Jack.

> One of the oldest traveling wave antennas is the horizontal rhombic.

==========

The terminating resistor has NO effect on the radiation pattern of a Rhombic in the desired direction of transmission.

If unterminated a Rhombic radiates and receives equally well in the opposite direction. The radiation pattern is bi-directional.

The antenna is terminated only to suppress radiation and reception in the reverse direction. The power which would be radiated in the reverse is absorbed in the termination. The enemy and the competition can't hear you. And you do not cause interference to other services in the opposite direction.

When receiving in the terminated condition the signal-to-noise and interference ratio in the desired direction improves by a few dB.

If a unidirectional beam is desired then a Rhombic could be considered to be very wasteful of Tx power - 1/2 of it disappears in the termination. There are more efficient ways of achieving the same horizontally-polarised objective (but perhaps less compact).

Never have more that 360 degrees in bends in the run otherwise you
should install a pull J-box. With careful planning you should be able
to achieve a nice run with few bends or install a pull j-box just at
one end before you do the final bends to get the conduit to where you
require it. The j-box could double as a ground plate holder or
transition from hardline to flexible coax junction.

There are several cable lubes out there, They are nasty, slippery to use but do work well. Most electrical supply firms have conduit pull lines or one might consider submersible well pump rope to use as a pull line.

The easiest way to make one of these antennas is to find an old set that is set up for 11 meters. However, if you decide to build one from scratch, it can be done by following the picture. You will need, in addition, to the antenna a relay box and a control box to electrically switch the elements direction. These boxes can be fabricated form parts available from local supply stores. To build these you will need one of the original super scanner instruction manuals which contains the diagram showing the relay switching.
This antenna offers omni and three (3) direction operation. Rejection is good. Direction is good. I have used mine for my base station antenna and works well on low and high power. Please refer to the picture for dims and lengths.

Enjoy, 73 KB9RPS, Steve

Henry Kolesnik wrote:
"---Dan, N5AR was travelling down an interstate and lightning hit the 2 meter whip on his van and blew the antenna, coax, and radio to pieces---."

It is likely N5AR`s 19-in whip and appurtenances would have been spared if he had 36-in extensions of grounded whips at the corners of his van`s roofline. The air terminals made by these corner whips would have relieved the short 2-meter band whip of stress.

It is surprising that the lightning created such havoc, especially if the antenna was not a mag-mount but was mounted on a through the roof fitting. The spacing between center conductor and roof or inside the fitting or coax is so small. RG-58 breaks down at not much more than 1400 volts peak. Evaporation of the antenna fitting or coax at the fitting should have kept the lightning from the radio.

Impedance and velocity factor discourage lightning propagation inside coax. A gas tube may save a radio from an antenna contact with a power line, but it`s superfluous for a strong lightning transient in every case I`ve seen. First problem is the delay in gas firing time. In power and audio circuits, capacitance can slow the voltage rise giving the gas tube time to fire. This is an unavailable tactic in an r-f circuit.

Best regards, Richard Harrison, KB5WZI

I am contemplating purchasing a High Sierra screwdriver antenna to mount on the rear of a motorhome. Does anyone have any experience with this antenna?

Would you recommend something different?

Thanks

Bill Grimwood

Forgot to mention I always use hardline so the cable does not generate
'loops'.
At the end of the messenger I have a 'Keller' wire puller which is an
expandable and retractable mesh wire type tubing. This stops the end
of the coax bending at the pulling point and makes for an easier and
non snagging pull. (actually used the mower tractor to pull mine
thru.)
One day I will pull the discontinued forms of wiring

Message-ID: <IPCMa.19843$fG.9813@sccrnsc01>
Source record: 113690

My web site (www.n6rk.com) has photos of my 850 foot open
wire line feeder for my big vertical. I use 4 AWG stranded
insulated aluminum wire (XHHN) on 5 inch centers. There
is a 50 ohm to 450 ohm balun at each end of the line. Loss
including baluns is only tenths of a dB.

I considered the remote amplifier idea, but that requires
an amplifier at each antenna site. After you consider
all the alternatives, the open wire line is the way to go
for that kind of distance.

At "several" hundred feet, whatever that means, you may be
able to use 1 5/8 inch Heliax if you can scrounge roll ends
and don't have to pay real money for it. K9DX claims
to have done this.

FWIW, I just installed a new tower for a tribander only
100 feet from the shack, so I could just use big coax
like LMR600. I was originally going to locate it
back on the property but didn't want to fool with another
open wire line.

Hi OM,

First models (and perhaps even current ones) used popular battery
powered screwdriver motors to perform the tuning. An example of form
following function (both are cylindrical designs).

From URL: http://home.earthlink.net/~jimlux/radio/antenna/screwdriver.htm

Sez:

"Generically, the screwdriver antenna is a vertical with a tuning/loading coil adjuted by a cordless screwdriver . The bottom of the antenna is a piece of tubing big enough to cover the motor, the top is a straight whip. There are a bunch of firms selling plans or antennas, a search for "screwdriver antenna" will turn them up."

So my understanding is that at first homebrewers used cordless screwdriver motors to tune the antenna. The name stuck even though commercial manufactures may use a different motor.

But as my moniker indicates -- just guessin - educated tho !!

What do you do with an antenna cable when you are not listening. Should you ground it as well? I wonder, when lighting strikes the antenna, will it go to your mast and through the grouding cable to the earth or it will go to your radio, or both? If the antenna cable which goes to the radio inside the house would be grounded in the house, wouldn't that pose some fire risk, even though you have your outer part of the coax and mask grounded to outside source?

Do not use perforated pipe!
It collects mud plus presents jamming points for pulling thru

No, it's fine. I don't know what to tell you though. I start xnecview
with the --animation option, or select anim from the struct menu, and I
get the animation of the currents. I have no explanation for why it
doesn't work under FBSD, I don't have an FBSD machine I can test it on,
the ones I have are all servers :) Are you trying it with the test.nec I
supplied? Or rather, with the output file from that? I do know that nec2
needs to include the current info in the output for the anim to work.

Dear Phillips:
Many thanks for injecting a reality check!
The real cost of projects such as these has to include the cost for things going wrong (as well as the cost of doing the job right the first time). Insurance is the conventional way to do that. If nothing goes wrong or the owner is not collectable, that is one thing. When the owner is collectable and things go wrong, the "inexpensive" work becomes very expensive indeed. Can one say: bankruptcy?
It would be desirable to have a registry of firms willing to do tower work.

Thanks again, 73 Mac N8TT

oh, so you do have restrictions... i thought you liked your method because it was not constrained like the stead state solution is. i never said that a wave didn't require energy, i said that a line doesn't necessarily have to be 'possessing'(however a line possesses something is beyond me) any power or transmitting any power... unless of course your new 'possessive' term means that it contains energy.

the answer is trivial. 50 ohm line, 50 ohm load, 50v DC source. i see a 1A
peak standing wave and no reflections.

Amen. Don't even *think* about 2" PVC. Two coaxes and a control cable look small in a 2" pipe, but it is almost impossible to pull anything else through if there are a few bends in the pipe.

I drilled a bunch of holes in the bottom of my pipe. Don't know if it did any good, but my ground is not nearly as wet as your area.

Good luck

Bill

Trivial is right. The context is RF waves. But, of course, you knew
that already. Please feel free to try again.

now you are really digging for reasons to use your methods. in 'reality'
the steady state solutions are used every day and provide real world answers
with much less computational complexity than using the complete solution.
where do you think the basic thumbrules that we all know about 1/4 and 1/2
wave line impedance transformations come from? would you like to try to
teach the calculus needed to understand the complete solution of what
happens when you apply rf to a 1/4 wave stub to the average ham?? how many
of them do you think would be able to apply that method to a real world
problem? are you saying that the whole smith chart idea is worthless

because it doesn't carry through the noise transients you see in your detailed analysis? remember, the smith chart is based on steady state solutions, as are most of the common impedance transformation programs and other rf design tools in common use.

well, thats enough of this for me for this go around... time to go back to lurking and work on some real antennas.

Around here, in East Texas, more water flows into the pipe than flows
out of the pipe. *NOBODY* around here has a basement for obvious reasons.
Empty swimming pools have been known to float a mile away while emulating
a boat.

You are mistaken to think I am pushing my methods. What I am trying to do is understand the underlying physics. I don't care if it results in anything useful. I just want to understand.

> in 'reality'
> the steady state solutions are used every day and provide real world answers
> with much less computational complexity than using the complete solution.

I am not interested in shortcut answers to practical problems. I am interested in understanding the underlying physics. There is a big hole in the shortcut methods that don't explain anything of value to me. Phantom waves that exist without any energy are the stuff of religion, not physics.

> where do you think the basic thumbrules that we all know about 1/4 and 1/2
> wave line impedance transformations come from? would you like to try to
> teach the calculus needed to understand the complete solution of what

I am not the average ham, Dave. Did Einstein worry about teaching relativity to the average ham? When Roy asked me for a transmission line length and a load value, did I give him 1/4WL with a resistive value? No, that would have been too easy!

If you are not interested in the underlying physics of the discussion, then feel free not to participate in the discussion. If you are interested, then offer something of value to that discussion. Energyless waves are a paradox. There's got to be a better explanation than phantom waves.

Could this be a graphics-card X issue?

It's possible that the animation feature works on in an X Window
environment when the video card is set to 8-bit (256-color) mode,
using the graphic's card's color palette. On a screen of this sort, the
values written into the card's frame buffer are not the actual RGB
values - they are indices into a hardware translation table which
holds the actual color values.

It's possible to do color animation without actually redrawing the
pixels in the window - you just change or rotate the values in the
color palette (changing the pixel-value-to-color-mapping), and the
colors on-screen change automatically.

On screens set into "true color" mode (typically 16 or 24 bit modes),
the values written into the frame buffer are the actual RGB colors.
You can't animate a screen of this sort without actually redrawing the
area you want animated.

I'm guessing that Xnecview might animate OK on your system, if you
switch your X server into 8-bit indexed-color mode.

What you have described reminds me of an antenna that has been called a
"sloper". This would be a single support, guyed with 3 dipoles. The dipoles
all have open center stubs that lower the resonance to that required by a
reflector. The dipole in the desired direction is fed, and the other two are
left open as reflectors.

I haven't seen one of these in years, and have no idea of their performance.

Jim Kelley wrote:
> You didn't mention anything about stationary waves.

That's because staionary waves do not exist *in reality*. Every
standing wave that exists *in reality* possesses jitter that
can be measured. Use the delayed sweep on your o'scope and
run the scale up to nS while looking at a voltage minimum
point in a standing wave. Jitter is guaranteed. Jitter is
a *transient condition* which should be completely missing in
a steady-state environment - but it's not missing. Steady-state
exists *only* in human minds, not in reality. Therefore, there
is no real Catch-22 associated with it since the steady-state
model does NOT match reality. Sorry to burst your bubble.

Your steady-state shortcut model leaves out a very important
step in understanding the match point at an impedance discontinuity
in a transmission line. If it hasn't been defined before, it's high
time that someone defines it. I am reluctant to do so, but if it has
to be me, so be it. However, it will do me no good. I would much rather
that you obtain fame for this discovery. Think about how famous you
could be.

If it includes the constructive interference term, then let's add
the constructive interference term.

75W + 8.33W + 50W = 133.33W

Yep, I like it, but Dr. Best denied that is what happens. He said
the source somehow anticipates the increased need for energy and
increases its output accordingly. No reply to my question: "What if
the source is nine light years away from the interference." Before you
reply, consider that the 50W is defined as the "interference term",
and obviously being constructive interference, requires an equal
magnitude of destructive interference somewhere else, according to
Optics, by Hecht. Your hole just gets deeper and deeper with every
posting.

Hi Cecil,

Your track record is miserable. To this date you have dismissed or
deflected all criticism and ignored contributions that did not conform
to your thesis. Your habit of blaming the reader is one that is most
pernicious and reveals how hollow your purpose is.

Inviting a correspondent to
>>>then feel free not to participate in the discussion.
is cynical and does not move you one jot away from your poor writing
style. You could have just effectively not responded and allowed the
writer to pursue or abandon the topic according to his own
inclination. To presume this negative offering upon him is simply
condescension.

Your included mandate
>Same goes for you.
imposes no obligation on me. Given you continue to be an unreliable
correspondent, then I am not interested in playing your foil to
propagate your brand of myth.

And plan on some sort of tuner so your transmitter
can load. The feedpoint resistance will be so low
that your transmitter will not se a load. They
work great, but you will need a small tuner or
matching network to get any power into it in the
first place. Then if you take the length of the
radiating elements as a fraction of 65 feet and
multiply the power out of the transmitter by that
you will get an idea of what your erp will look
like. That said years ago I used a FT7 with 15
watts out into that set up and was pleased with
the results, once I started using the matching
unit.

No, but wave cancellation does. And when wave cancellation occurs, the energy in the canceled waves cannot continue in the same direction and cannot be destroyed. When only one other possible direction exists, wonder what direction the energy takes? It ain't rocket science.

I assume that you have either city water, (lotsa pipe), a well (casing
down to water table) or tanks and trucking. The first two seem like
they would give a ground. What am I missing on this?

When you get a round tuit? The last job I worked was filled with triax, arcnet cable, thinnet, and utp along with 25pair telco. I was responsible for everything other than the 25 pair and nothing ever got pulled.

Now in another profession, I work maintenace and the spaces are filled with twinax, thinnet, Tbase2, 25 pair, and cat5 (abandoned) and cat5e (new stuff). Nothing has ever come down. I think I remember thinnet being 50ohm so maybe a piece or three might come down if it has radio use.

Then there are conduit runs with wires last powered in the 70's going to places that don't exist.....

Wire is forever...

no, it's physics... what is the wave equation that describes this
cancellation phenomena and the determination of the 'other possible
direction'??

Don't bet on it!! This thread is not DEAD!

There are some very good physics questions and principles being discussed here. Some questions have been posed that are challenging to the physics community.

Comments that are Ad Hominem don't add to the discussion and only detract from the discussions. Let's stop the personal attacks and try to understand what happens to the energy!!

I read the posts and think about what is being said. I don't have an answer. But I know that some really sharp Physicists are reading the significant parts of this thread and pondering the question that has raised.

I'm interested in a good answer based on Physics. I would like to see the question resolved.

I quote a comment from a recent post and I hope it is not true.

No! They just have a coil! Your friend will need a 'stinger' that
fastens to the top of the RM-75. The Hustler mobile antennas are
designed for a working length of 7 to 8 feet. It's length is adjusted to
bring the antenna to resonance. A good antenna analyzer will help at
this point.

There is another post that states a tuner is needed and that is correct.
The feedpoint impedance is very low and the tuner will allow a match for
reasonable power transfer to the antenna.

This is a very succinct statement of what I feel is the fundamental problem with Cecil's analysis. Only average powers are being dealt with, and all information about the time variation and movement of power and energy is lost in the averaging process.

>>The mother science of RF, Optics, has always had the answer:
>> "Optics," Miles Klein, John Wiley & Sons,
>> Chptr. 5.2 "Two-Beam Interference"
>>page 185 shows illustration for "Intensity Distribution" that you can
>>do for yourself with simple math:
>> I = 2 * I1 * (1 + cos(phi2 - phi1 - delta))
>> ave(I) = 2*I1 for an integral number of waves
>> where:
>> I: The intensity over the variation in phase (delta)
>> I1: The intensity of each, coherent source (being equal)
>> phi2: source2 phase (fixed over interval of delta)
>> phi1: source1 phase (fixed over interval of delta)
>> delta: vary phase to observe full 360ï¿½ interference pattern
>>

Per my source, "Optics," Miles V. Klein:
"...we shall use the generic term "intensity," I, instead
of the more correct, and awkward "flux density,"
"radiation incidence," or "irradiance,"

"Radiant Incidence" is expressed in terms of watts/mï¿½

This math represents a total statement covering all issues of
interference for any form of radiation in any situation. Simpler
solutions that abandon phase to scalar representation also abandon
access to a phase argument.

When you see the two (simplified math and phase) mixed in an argument
that FOLLOWS the loss of phase information, you will also find answers
that are not sustainable in practice nor theory.

The formulas from Optics are not generally used in our field, but the
math is from Maxwell's observations that preceded the introduction of
RF by decades. Historically, even his work is derived from others
that long precedes RF. Either way, our community observes the same
physics and simply couches the expression in terms related to our

field. The Math is not so dense nor impractical to evade simple comparison.

Good luck fellows.

Michalkun wrote:
"What do you do with an antenna cable when you are not listening?"

An amateur has an option to avoid operation during troubled times and to disconnect equipment during those times and during times he won`t be available to choose to disconnect.

I worked decades with commercial installations which operated 24-7 and could almost never be disconnected.

An outside antenna connected with equipment inside often is disconnected by the amateur when not in use and he tosses the cables outside. This is usually quite safe and requires little worry about grounding the lightning bolt. It will find its own way. There are more elegant grounding schemes, but few are more simple.

An antenna on a grounded conductive support will likely shift most of the surge current to the support. The antenna cable almost certainly has higher impedance than a supporting structure to which the coax shield should be grounded at the top and at the botton of the structure. The structure base should be well grounded immediately onsite.

For highest protection, the goal is minimum potential difference as the result of a surge. This is the point of bringing the antenna ground, power system ground, and equipment grounds together at the point where the antenna cables enter the shack. The instantaneous voltage on all grounding systems should rise and fall together keeping the risk of injury or damage low.

Best regards, Richard Harrison, KB5WZI

From: Roy Lewallen <w7el@eznec.com>
Message-ID: <vg6vu9huocpc4e@corp.supernews.com>
Source record: 113637

The question is: what's the question that's to be resolved? I fear it was lost long ago, somewhere along the path from transmission lines to optics, quantum physics, scattering parameters, and personal insults.

If there are indeed two conflicting interpretations of observable physical phenomena, surely one or both parties can produce an example or experiment whose results can be adequately explained with one method and not the other.

I'm not aware of any transmission line problems that can't be solved completely using conventional and accepted methods. Engineers have been doing so for over a century now, producing predictable results and devices that reliably work in practice. As far as I'm able to determine, Cecil is proposing that there's something deficient with the methods that have been used for this period. So it seems to me that it's up to Cecil to produce an example or experiment that demonstrates how the existing methods are wrong and will produce an incorrect result, while his method will lead to a verifiably correct result.

A traditional forum for presenting ideas that advance the level of understanding is professional publications. I encouraged Cecil earlier to write up his analysis for an IEEE publication. Hopefully, he's pursuing this and we can all look forward to seeing a paper that's been professionally reviewed.

It's hard to tell for sure, but superficially at least, it appears that Cecil has failed to convince many of the active participants of this newsgroup of his interpretation. It might be because of an inadequately clear explanation, it might be because we're particularly dense or ignorant, it might be because we've been "seduced by the steady state" -- or it might be because Cecil's wrong. A professionally reviewed paper, which would invite responses from true experts, worldwide, would certainly be a positive step in sorting out which possibility is true.

All I can tell you is to ask owners of screwdrivers with that thin
"don't-squeeze- the charmin' stuff.
It is will crack and split within a year. The Lexan is 1/8" wall. It
takes YEARS for my covers to
even fade to a slight dullness much crack and split. I have one on my
personal vehicle (Cyclone II)
that is 6+ years old. It has stayed in the sun, snow, rain, 0 temps, and it
is still good. If I wanted to
skimp on material I WOULD use that thin stuff, but if I want my own antennas
to be protected from the WX, then I want the others I make to be long-lived
for customers.

Richard, please apply that math to the following experiment. We have
a two watt laser emitting coherent light. The beam is broken into
two one watt beams. One beam travels 180 degrees farther than the other.
The two beams are then recombined along exactly the same vector path
such that the waves cancel 100%. What happens to the energy and
momentum in the two canceled beams?

Jim> the current info in the output for the anim to work.

Dave> Could this be a graphics-card X issue?

Doubtful, as I've tried multiple cards.

I finally remembered how to make screen dumps, so here's what I see:

http://www.twilley.org/~jmt/animate.jpg

That's what's on my screen when I zoom in on the antenna and select
'anim.'. The command line includes Jim's test NEC input file and the
output file generated by my local nec2dx build. Those files are also
available at:

http://www.twilley.org/~jmt/animate.nec.gz
http://www.twilley.org/~jmt/animate.out.gz

The output file is roughly 1.5M compressed.

It's possible that my nec2dx build is doing something wrong, but I'm
pretty sure that's not the case.

Jack.

So Roy, what do you think is the mechanism by which all the rearward-
traveling reflected power is 100% re-reflected back toward the load
in a matched system? Please be specific.

Source record: 113644

Jim Higgins <UseAddressBelow@pandora.orbl.org> wrote in message >
> I should have asked if the stock tubing used for the Carolina
> Cyclone can survive a whack with a hammer.

If I am anything I am honest. The short answer is NO! But why would anyone want to do
that? The cover is supposed to protect the motor and drive system. Many people like the clear
covers and seem to prefer them. I have had gravel slung on to my personal antenna cover and it
made a little "ding" or scratch on it. It takes a solid thwack to break one, but I have been using the
stuff for years--took a lot of experimenting to find the right combo. I am not a plastics engineer, I
just use what works. I have been making antennas since 1993. I recently took one back in trade that was built around '94 or so. In those days, I used stainless steel for the lower masts because it
was more durable. (The customer wanted a larger diameter coil.) The old DK3 style with PVC
and the usual construction techniques still looks like new and the cover still looks fine.I kept it because it looks good and I have it on another vehicle.

Anyone who stays with a product makes changes. The Cyclone I has evolved. For one thing, I
didn't want to copy the generic DK3. I wanted something that would handle power, look good
while doing it, and provided value for the price. I felt (and still do) that screwdrivers cost too much.
I know how much it costs to make one.

Over the years I have had quite a few arguments with engineer types who criticize my materials. I
had to change to aluminum because stainless costs too much. Some argue that one should only
use copper. I found that aluminum, copper (yes, I have made some with copper), and stainless
work about equally well. People argue over PVC (bad), Micarta, and Nylon. I use a kind of
black Nylon that works well and costs less. The Micarta is more expensive and comes off the
lathe in long, messy strings that have to be cleaned up after turning. I have had people criticize
me for using the Nylon. Can I tell you exactly what's in it? No. But my plastics supplier can.

I can tell you this: I'd hate to get smacked with a stick of it--that stuff is HARD, and almost im-
possible to break.

It all boils to this: No one can please everybody. Someone is going to complain, even it is just for
the sake of complaining. Just read EHAM, and read my reviews from 2 of my customers.

Irradiance in optics is "only average powers" and optical physicists
don't seem to have any problems with it, Roy. In fact, the Poynting
Vector is an energy averaging process. Instantaneous energy in EM
waves is not very useful and difficult if not impossible to measure.

From _Optics_, by Hecht: "Since the the power arriving cannot be measured
instantaneously, the detector must integrate the energy flux over some
finite time, T... If T is divided out, a highly practical quantity results,
one that corresponds to the *average* energy per unit area per unit time,
namely, I (irradiance)."

Forward power and reflected power in a transmission line are similar to
irradiance in optics.

You've failed to convince me that there are one or more waves of average power traveling and reflecting within a transmission line. So your question is something like asking me to explain the mechanism by which ghosts levitate.

Can you propose a problem which can be solved to yield a demonstrable result only if such an assumption is made?

> direction'??

There's only two directions in a transmission line. If RF energy exists
and it is not flowing in one direction, it is flowing in the other
direction. Does that sound like rocket science?

Wave1 = 35.36V at zero degrees and 0.707A at 180 degrees = 25W

Wave2 = 35.36V at 180 degrees and 0.707A at zero degrees = 25W

Wave1 superposed with wave2 = 0V and 0A. What happens to the energy?
Does that sound like rocket science?

From "Transmission Lines and Networks", by Walter Johnson.
"P = |E+|^2/Z0 - |E-|^2/Z0"

Power delivered to the load equals forward power minus reflected
power.

Johnson continues: "We can regard the first term in this
expression as the power associated with the forward-traveling wave,
and the second term as the reflected power (associated with the
rearward-traveling wave)"

What do you think a Bird wattmeter is reading?

What is voltage times current when they are in phase?

How much power will a 50 ohm load accept from a 150 ohm
feedline with 100W of forward power?

Huh? The first two texts I looked at (King, Mimno, and Wing's _Transmission Lines, Antennas, and Wave Guides_, and Kraus' _Electromagnetics_), define a complex Poynting vector, which is time varying. I think you mean that instantaneous energy in EM waves is inconvenient so should be discounted and ignored.

Cecil, you're very skilled at agressively deflecting an argument away from an area that's difficult for you, but I won't play that game. Where's that example or experiment? Or is the Bird wattmeter, a voltage-current reading instrument with a meter calibrated in watts, the only example you can produce? Do you claim that the reading given by a Bird wattmeter can be explained only by assuming the existence of traveling and reflecting waves of average power which follow your rules of interference and direction reversal?

I am, of course, referring to the time-averaged Poynting vector which
is equal to 1/2 Re(ExH*). Why does a ham need to know the instantaneous
energy in EM waves? What is the use of such a value? Hecht, in _Optics_
says that instantaneous power in light waves cannot be measured.

A person (ham or not) needs to know the instantaneous energy in EM waves
if he's to understand where and how energy flows in transmission lines,
and to keep from being misled by oversimplified analyses. Fortunately,
hams generally only have to deal with power entering and leaving a line,
which can be easily calculated without knowing either the instantaneous
or average power or energy anywhere within the line.

Sarge,
You would need something like 135 feet of wire, and three
insulators. Make the feed point about 33% from one end.
Depending on the lind of feed line you plan to use, that's
about it. I'd figure on needing a tuner too...

You can probably buy one cheaper than you can make it. Try Radio Works at www.radioworks.com to see what they have available.

If you want to make a ladderline fed windom, cut the horizontal element for 80m, and feed 14% off center.

A total single wire windom is done the same way, except only one wire is used all the way to the shack. This one must be worked against a good ground.

Cecil:

[snip]
> The Conservation of Energy principle indicates that the energy flowing
> into the impedance discontinuity must equal the energy flowing out of
> the impedance discontinuity. Therefore:
[snip]

No it doesn't! That statement is a fallicy. Energy doesn't flow and it
often disappears!

To see that, all you have to do is to consider a charged capacitor
containing a fixed amount
of energy E, which is subsequently instantly connected across an identical
capacitor containing
no energy.

Calculate the total energy in the two capacitors before and after they are
connected you will find
that the initial energy in the two capacitors is E and the final energy is
E/2.

What?

The radiation resistance will be in the range of 1 to 2 ohms. The ground losses will be in the range of 10 to 20 ohms.

When tuning the antenna using an analyzer tune for zero reactance at the frequency of interest. Change the length of the stinger 1/16 inch at a time. The ground losses will dominate. Efficiency will be around 5%.

A tapped coil at the base will also serve as a matching device instead of a tuner.

See the ARRL Antenna Handbook chapter 16 for more details.

Do a search for Cebik -- I think his call is W4RNL. He has an article
on off-center fed dipoles, that is, Windoms, and compares them to
center-fed dipoles.

But to make an exact replica of the "Carolina Windom" that Radioworks
sells, it'd be cheaper to just buy theirs. See their web site.

> --
> 73, Cecil http://www.qsl.net/w5dxp
[snip]

Notwithstanding their labels and nomenclatures, Bird wattmeters do not read power!

In reality, Bird wattmeters provide an "indication" of the derived quantities commonly
called reflected voltage [B = V -RI] and incident voltage [A = V + RI] computed
by their internal analog computation circuitry from the fundamental quantities of voltage
V and current I on the line at their point of insertion.

Reflected Power is an unfortunate misnomer and is a ficticious quantity used only to
facilitate certain transmission line calculations. The term "Reflected Power" was never
meant to be taken literally by its' originators. Subsequently uninformed "zealot's" such as
yourself and the wonderful Maxwell have taken this literal interpertation of Reflected Power
and its' "religious" interpertations much to far! :-)

The use of this pseudonom "reflected power" for interperation of the actual physics and
dynamics of electrical transmsision waves in the manner you are proposing is incorrect and
fraught with many possible pitfalls. Please don't "engineer" any Saftey of Life
systems using your allegorical mis-interpertations of "reflected power".

Power has units of energy per unit of time [Joules/second] and as such reflects only
a steady state view of the world i.e. a smooth flow of energy. Power cannot be
stored like energy since power is a derived "flow" quantity, i.e. a flow of the
fundamental quantity called "energy".

Energy on the other hand can be reflected and stored and a proper and correct
mathematical analysis of reflected energy transient dynamics is exactly correlated with
actual physics and measurements and can be easily carried out using LaPlace Transform
techniques [Once called Heaviside's Operational Calculus].

During the steady state there simply is no power sloshing about longitudinally
from end to end of a transmission line, instead during steady state the line has stored
the energy it took to charge the line as potential energy in its' oscillating magnetic
and electric fields [i.e. in its' distributed capacitanceand inductance] which thus "sloshes"
back and forth transversally from side to side [so to speak] on the line. All the
while energy is being continuously delivered in one direction only from prime mover [source]
to load unidirectionally down the line. [Unless of course there are prime movers
at each end of the line in which case power will/can flow simultaneously in both
directions.] There is no such thing as a reflected power flowing continuously
back down the line and recirculating longitudinally! That just does not happen
in the steady state!

Additionally there is no such thing as a "power reflection coefficient" as you have
called it.

There is only "The Reflection Coefficient" which is defined on an
impedance basis [i.e. based upon V and I] namely RHO = (R-Z)/(R+Z) where
R is the "reference impedance" and Z is the impedance "faced" by R.

In terms of the voltage V and current I at a reference plane [point] on a transmission
line the so-called reflected voltage wave is B = V - RI a derived quantity not actually
existing on the line, and the incident voltage wave is A = V + RI, another derived quantity
not actually existing on the line, and it is very easily shown that B =

RHO*A with RHO
as defined above. A and B exist only withing the Bird's so called wattmeter circuitry.

By the way, RHO(p) is a complex function of complex frequency p since in general
both driving point impedances R(p) and Z(p) are also functions of the complex
frequency "p = s + jw" and RHO(p) can be readily transformed [Fourier or LaPlace] into
a time domain impulse response function rho(t) which can be used to calculate exact time \
domain echo responses in the transient domain which correlate perfectly with measurements.

BTW... you are in error in most of your equations since, RHO^2 is not mathematically correct
in your equations and is simply not a quantity of interest. The quantity of interest in the Feldtkeller
power relationship is RHO*(complex conjugate of RHO) NOT RHO*RHO.

Cecil, stop being "reckless with mathematics" and do a little more research before promugating such questionable and potentially misleading metaphors of reflection dynamics.

Best regards, ;-)

The other E/2 is radiated! So, E = E/2 + E/2; all energy is accounted
for!! And it is RADIATED!! [Many an EM test has failed because of that
radiation.]

IIRC, thinnet was RG-59 (73 ohms). Good stuff for dipoles.

Our location threw away (after great expense for pulling it) tons of RG-62
(90+ ohms) used for 3270 terminals.

Next to go will be tons of "token ring" cable -- STP.

It's not nice to imply that I said something that I never said. Here's
what I specifically assert at the beginning of my article:

"Note that this is *NOT* a new and different method of system analysis.
The ONLY purpose of this paper is to illustrate how to track the energy
at an impedance discontinuity point in a transmission line."

What is it about, "This is *NOT* a new and different method of system
analysis" that you don't understand?

I have asked you to present an example of standing waves in a single
source, single feedline, single load system devoid of reflected waves.
So far you haven't done so.

Reflected waves possess energy. Energy flowing past a point is defined
as power by the IEEE dictionary.

> Energy on the other hand can be reflected ...

What happens to the energy in canceled waves that are destroyed?

None of my references deal with anything except average power. Virtually
all references to power use RMS values of voltage and current. Even
"PEP is the *average* power supplied ... during one RF cycle at the
crest of the modulation envelope ..." The very existence of a delta-t
term for power implies an average value over that delta-t time.

233. A G5RV of excellent quality ?

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-03 15:20:05 UTC
From: Thierry <lombrytNOSPAM@hotmail.com>
Message-ID: <3f0449a1$1_1@news.vo.lu>
Source record: 113577

Hi,

There are several manufacturers or multiband dipoles (i.e.G5RV) between
Universal radio, USA2Way, WIMO, etc, including some variant like W3DZZ, etc.
Prices are also flexible from $30 - $140 !
I prefer to buy one in place of building it.

I am looking for a multiband G5RV able to work between 80-10m and supporting
1 kW (so about 31m long).
According your experience what should be the best brand considering VSWR,
quality of material, longevity and resistance to UV, etc, easy to setup,
quality insolators, robustness of the wire and its accessories ?

Thanks in advance

Roy, W7EL wrote:
"A person (ham or not) needs to know the instantaneous energy in EM waves if he`s to undrestand how energy flows in transmission lines---."

Further discussion has involved the Poynting vector which never concerned me on transmission lines.

If you sum all the power passing through an imaginary bubble having a fixed distance from an enclosed radiator, the total must equal the total radiation. If the radiator is not isotropic, each equal area of the bubble won`t have the same power passing through.

The reason for stating the obvious above comes from Cecil`s and Roy`s mention of the Poynting vector. A vector has direction in addition to magnitude. The difference between a vector and a phasor is not very important.

When we use vectors to describe an alternating voltage, current, or the fields they produce, all we need is consistency in picking peak or rms but when we calculate power we use rms volts and amps or we multiply peak volts and amps and divide the product by 2.

There is power in magnetic and electric fields. A magnetic field turns a motor. An electric field sucks electrons to the plate of a tube. Time varying fields can reproduce each other, causing radiation. So, it`s natural that in a propagating wave, each field, electric and magnetic, has equal strength, that is, 1/2 the total energy.

The propagating wave has a strength experessed in volts per meter. In free-space, the radiation field declines linearly along any radial from an isotropic source. That is, if the strength at one mile is one volt per meter, the strength at two miles will be one-half volt per meter.

Power is E squared over R. The resistance of free-space is 377 ohms. Power in a 1V/mtr wave is 0.0027 watt per sq.mtr.. Power in a 1/2V/mtr. wave is 0.00067 watt per sq.mtr..

The Poynting vector is a vector which defines the direction of energy flow as well as its magnitude. Its magnitude at a point in space depends on propagation pattern among other factors.

The magnitude of the Poynting vector is given in watts per square meter under specified conditions by King, Mimno, and Wing in their equation 44.2.

A vector represents a wave magnitude as a fixed length, not as a continuously varying quantity in most cases. That`s what prompts my

response to Roy`s instantaneous energy in EM waves remark.

Best regards, Richard Harrison, KB5WZI

How did it become MY model? I think it belongs to everyone. :-)
The problem with your model is that it relys on non-existant physical
phenomena. Makes it kind of a tough sell to realists.

It can be expressed in units of power, just as the vertical potential energy in a projectile at the highest point in its trajectory can be expressed in the same units as kinetic energy.

> > Energy on the other hand can be reflected ...
>
> What happens to the energy in canceled waves that are destroyed?

Energy exists only where the waves exist. If there is no path for the wave to propagate, no energy is transferred by those waves, and the energy stored in the line continues to oscillate between the E and H fields (as Peter explained), stimulated by the boundary potential.

Hi Cecil,

The math is complete. Do it yourself. You will discover that you
have, as usual, misbounded the question. If you cannot accept your
mistake, no amount of computation on my part will be accepted by you
anyway.

As for what happens to momentum, to put it succinctly, don't go where
you are unprepared to visit. (It also suffers from the lack of
bounding.) This immaterial inclusion of yet another phenomenon is
further example of poor writing where you guild the lily. It lacks
any introduction by you to present its relevance. This is a lack of
focus that is certainly within the venue of newsgroup activity, but
when I challenge you on it, you scuttle under a rock complaining of
that same lack of relevance. I see no reason to pursue an agenda you
refuse to attend after you once introduce it.

Not at all. It's entirely consistant with my claim. Do I need to write the equation for the reverse direction too so that you can see that too? There's no energy "turning around" in those equations. Different waves are involved in each case.

And I still don't see how lengthening the transient period makes any difference.

If you are looking for a G5RV that will cover all the ham bands between 80m and 10m, you will be extremely disappointed. The G5RV was designed before the WARC bands were available. Here's the theory behind a G5RV:

The G5RV works on 20m, the band for which it was designed, because it is 1.5WL long and fed with 1/2WL of balanced line.

On 40m, the G5RV is 0.75WL long fed with 1/4WL of balanced line. The 1/4WL feedline *IS* a 1/4WL transformer for the high impedance of the 0.75WL dipole.

On 80m, the G5RV is 0.375WL long fed with 1/8WL of balanced line. Take a look at my web page to see that this is a pretty good match.

On 15m, the G5RV is 2.25WL long fed with 3/4WL of balanced line. Not a good match.

On 10m, the G5RV is 3WL long fed with 1WL of balanced line. That's bad news.

Those were all the HF bands that existed when the G5RV was invented. It is a complete accident that the G5RV works well on 12m. It is a complete disaster on 30m.

So you can expect your G5RV to work well on 80m, 40m, 20m, and 12m. That's not bad but it's a far cry from an all-band antenna. OTOH, on my web page, I describe how to turn a 130 ft dipole into a true all-HF-band antenna by simply varying the length of the feedline.

Incidentally, by varying the length of the G5RV matching section, one can obtain a relatively good match on all HF bands.

Hi Andy,

A tuner will tune any antenna (as long as the antenna/system does not
present reactances that cannot be accommodated). You might ask
yourself why the manufacturer would willing impose a condition that
was frequency related. The answer may devolve to how much loss are
you willing to accept in attempting to tune the antenna? Then you
need to translate that loss into heat burden for the tuner, and what
is its capacity to hold heat. Will it delaminate a board? Char
components? Melt solder? It may not flame, but it may be ruined far
in advance of that final stage.

There is also the question of metering and control (I presume this is
an automatic tuner that is a companion for another piece of
equipment.) At higher frequencies, the metering/control may lose
sensitivity, and at some frequency that circuitry will fail totally.

Hi Thierry,

Buy locally because the only thing of value you will obtain is the
right to gripe about it failing. Why pay more for excessive postage
stateside, exchanges, repeated attempts to contact the vendor? If it
doesn't fail, then you got your money's worth. If it does, you can
meet them with the charred remains and humble them.

So does yours, Jim, about six non-existant physical phenomena at
last count.

> I think the all the fame for research
> on this subject has already been served up and properly accredited.

I'm not looking for fame, just answers to questions that you and others
refuse to answer. One wonders why you don't answer my questions. One
wonders why I cannot find answers to my questions in any of my references.
Here's one of of my questions again. Please answer in classical physics
terms of wave models.

We have two watts of coherent, single-frequency light sourced from a
laser. We set up an inference exercise by dividing that single two-
watt beam into two one-watt beams. We do whatever is necessary to
get those two beams to be 180 degrees out of phase. Then we do whatever
is necessary re-combine them along an identical vector path. Just before
the re-combining, the two waves each possessed energy and momentum. After
the re-combining, the two waves disappear through 100% cancellation. What
happens to the energy and momentum pre-existing in those two waves?

You are always telling me to read the material, Jim. Why don't you
take your own advice. You cannot possibly understand the context of
the present discussion unless you have read Walter Maxwell, Jon Bloom,
and Steven Best. Why do you choose to remain ignorant of the context?

> And I still don't see how lengthening the transient period makes any
> difference.

Your proposed waves have to be smart enough to know whether to carry
energy or not. You say if the energy is going to be dissipated, the
wave carries energy. You say if the energy is not going to be dissipated,
the wave carries no energy. If the energy is coming from Alpha Centauri,
the waves have to be smart enough to predict the future 9 years ahead of
time and know whether to carry energy or not. Your proposed smart waves,
smarter than you or I, are a gigantic hole in your assertions. Another
gigantic hole in your assertions is that EM waves can exist without energy.

Averaged over one cycle, in order the the energy per unit time comes out
correctly.

> Instantaneous energy in EM
> waves is not very useful and difficult if not impossible to measure.

Instaneous voltage peaks aren't that difficult to measure any more, and
are just as useful a term as other way of expressing sinusoidal
waveforms.

> Forward power and reflected power in a transmission line are similar to
> irradiance in optics.

Due simply to the fact that the units go as the square of the electric
field in both cases. What are you inferring from that?

Most of us use the time-averaged Poynting Vector. Roy introduced the
instantaneous Poynting Vector which obviously exists, but AFAIK, has
very little usefulness. As Hecht says, in _Optics_, "Furthermore, since
the power arriving cannot be measured instantaneously, the detector must
integrate the energy flux over some finite time, T."

249. Re: Conservation of Energy

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-03 18:16:32 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <vg8snst4h2a359@corp.supernews.com>
Source record: 113592

It's not necessary for something to be a phasor or a vector -- it can be one or the other, both, or neither. And they're not the same.

A phasor quantity can have physical direction. Therefore, it can also be a vector having X, Y, and Z coefficients (that is, coefficients of unit vectors i, j, and k) describing its orientation and/or direction of movement, in addition to its vector-like real and imaginary values describing amplitude and time phase. An example of this is an E field radiated from an antenna being driven with a sine wave. It has both time phase and directional orientation, and so can be described as a vector phasor. A phasor can be a (physically directional) vector, or it can be a scalar. An example of the latter is the voltage in an AC circuit, which is a phasor but not a vector. And, a directional vector can be a phasor, DC, or have any other time relationship. For example, the E field from an antenna driven with a square wave is a vector, since it has a physical orientation and direction of propagation -- but it can't be described as a phasor, since it's a complex time waveform. The H field of a permanent magnet is a vector, since it has physical orientation, but isn't a phasor, since it doesn't vary with time at all.

Which brings us to the Poynting vector. The Poynting vector is a time-varying quantity with a physical direction. But even if the component E and H fields are sinusoidal, the Poynting vector can't be described as a phasor in the same terms as the component fields. The reason is the same as why a power waveform can't be described in terms of constituent V and I phasors -- there's an implicit time-varying factor contained in a phasor, and the period is different for the power waveform than it is for the V or I waveforms. So the implicit frequency used to describe V and I as phasors is wrong for the power waveform. The Poynting vector has the same problem with being described in terms of E and H phasors.

One can, of course, calculate an average value for the Poynting vector, just as you can calculate the average value of power. The average value of both these quantities is useful for many or most purposes. But to see where the power or energy is really going requires use of the time-varying values.

Over a cycle, the Poynting vector changes amplitude, and it can reverse direction -- just like a power waveform. (It is, after all, a power waveform with physical direction.) In the case of a purely reactive field, for example, the Poynting vector will point inward as often as it does outward, revealing that power is being moved through the observation surface and back each cycle. It will average out to zero, but knowledge of that movement of power is lost in the averaging

calculation.

Richard, the equation you reference in King, Mimno, and Wing is the magnitude of the Poynting vector. The complete time-varying value of the Poynting vector is given by the preceding equation, 44.1.

The only reason I mentioned the Poynting vector was in response to Cecil's statement that "In fact, the Poynting Vector is an energy averaging process." He later said that, of course, he was talking about the average Poynting vector. Well, taking the average value of the Poynting vector does give you average power flow. But it doesn't tell you how much energy there is -- for exactly the same reason that knowing what speed you're going doesn't tell you how far you've driven.

Ah, so there is no experiment or example that can be constructed to test your theory by measuring observable results.

I wish you would have said this up front, instead of first tossing out the Bird wattmeter, then a couple of connected transmission lines, as examples that would.

Well, since your theory is untestable, it remains to be settled purely by argument. I'll gladly leave that to others.

Fair enough. I was thinking about something like a 12.5:50 ohm unun,
but a tapped coil would have better flexibility (and an ATU even more,
although its losses might be higher than a beefy coil with a manual tap)

> wave to propagate, ...

But there is always another path for the wave to propagate in a transmission line - the only other direction available. When a wave encounters a short circuit, the energy changes directions. When wave#1 encounters an equal magnitude, opposite phase wave#2 traveling in the same direction, the energy changes directions. There *always exists* the other path for energy. Otherwise, the Conservation of Energy principle would be violated.

If "energy exists only where the waves exist", how can waves exist without energy, as you have asserted numerous times? That's another one of your contradictions that you refuse to address.

It's not a choice I've made, really. I don't have a subscription to QEX, and the article isn't available online. In retrospect I guess you do have a point though. Reading your material does tend to leave one ignorant of the subject. :-)

> > And I still don't see how lengthening the transient period makes any

You see, this is where your blind-side leaves you wanting. You have never understood the expression 'transfer of energy'. The cancellation has nothing to do with how long the transmission line is.

How about an analogy? Cecil is sitting in Texas, and knowledge is being radiated toward him from some distant source. The knowlege arrives at Cecil's location, but Cecil blocks it out and the result is that there is no transfer of knowledge. :-)

That the "forward power and reflected power in a transmission line are
similar to irradiance in optics".

On the contrary, here's the experiment, repeated once again in case
you missed the last N times I posted it over the past N weeks:

We have two watts of coherent, single-frequency light sourced from a
laser. We set up an inference exercise by dividing that single two-
watt beam into two one-watt beams. We do whatever is necessary to
get those two beams to be 180 degrees out of phase. Then we re-combine
them along an identical vector path. Just before the re-combining,
the two waves each possessed energy and momentum. After the re-combining,
the two waves disappear through 100% wave cancellation. What happens to
the energy and momentum that pre-existed in those two EM waves?

Too bad the explanation is simply evidence of extreme seduction
by the steady-state model. :-) How can standing waves with energy
exist without reflected waves with energy? I have asked that question
at least a dozen times and the silence is deafening.

Feed the dipole with a balanced line feeder and
tune anywhere you want to. I cant get my 68'
dipole onto 160, but it works everything from 80
to 10 w/o complaint.

I have the article(s) on CD. If you will agree in writing not to reproduce
the articles in any manner whatsoever, I will loan you the CD.

> You have never understood the expression 'transfer of energy'.

I understand the expression, Jim, and I understand what a contradiction
it presents for you. Given two of the ways that waves can cease to exist,
the energy can, 1. be transferred to a resistor or, 2. be transferred to
the point of wave cancellation. But you cannot allow energy to be transferred
to the point of wave cancellation. Therefore, you cannot allow any energy
in your waves that are going to be destroyed by wave cancellation. Therefore,
your waves have to know ahead of time whether they are going to be destroyed
or not. Your waves have to be smarter than you are. Even though they carry
identical voltages, currents, and phases, the waves that will be dissipated
in a resistor possess energy and the waves that will be destroyed by wave
cancellation possess no energy. That's supernatural stuff, Jim. Sorry, I
just don't buy it. Waves carry whatever energy waves carry. If they cease
to exist because they encounter a resistor or because they engage in wave
cancellation, they give up the same amount of energy in the process.

You will be pleasantly surprised at how little RF
you need to radiate to be heard. But you have to
give your radio a load to work against. Cross
polarization will be a problem for local contacts,
but makes no difference once you start to bounce.
HAVE FUN!

> to the point of wave cancellation.

It IS transferred there, but only during the transient period.

> Therefore, you cannot allow any energy
> in your waves that are going to be destroyed by wave cancellation.
Actually, your energy model is the one with the problem in that regard.

> Therefore,
> your waves have to know ahead of time whether they are going to be destroyed
> or not.

You've got the wrong picture in mind. Picture the oft used water pipe
analogy. The energy source is the water spigot at one end. Water
pressure is the energy. The other end of the pipe is blocked, i.e.
there is no outlet for EM wave energy. (We'll assume the pipe is under
a vacuum, or ignore air pressure.) When the spigot is opened, we begin
the transient period, and that lasts until the water reaches the
blockage. At that point the spigot maintains water pressure within the
pipe, but the water stops flowing, i.e. the energy from the spigot
reaches no farther than the blockage. If spigot is closed and the
blockage is removed, water pressure energy in the form of the flow of
water is conveyed beyond that point to whatever terminus happens to
exist until the pressure drops to zero. Or, if the pressure to the
spigot is removed, water will backflow through the spigot until the

pressure in the pipe goes to zero.

> Your waves have to be smarter than you are. Even though they carry

Don't know about a 6m antenna as I don't have one. But I just tried the AT-11 with my 40/80 m
dipoles and the best that it could do was 3:1 VSWR. So then I tried the FT-920 internal tuner which
could get the VSWR down to < 1.5. Even called a station in Arizona that I heard and made contact:
I'm in the SF Bay Area. Efficiency was probably < 10%, antenna pattern less than optimum, but when
the band is open, anything "works".

That's very similar to the experiment I used to show you how your model
is wrong. Only I described how all the light moves from place to
place. That's missing from your "experiment". The question has already
been answered - just like all the others. Why not explain what you
think happens to the energy? Maybe you have it right by now.

We know that a wave (or some part of it) changes direction when it
encounters a physical discontinuity. But you continue to fail to
explain how a wave changes direction when it encounters an equal
magnitude opposite phase wave #2 traveling in the same direction.

Can you show the Poynting vector turning around? That would be a
reasonable proof. But you've provided no specific mechanism for
accomplishing this feat of magic.

> There *always exists* the other path for energy.
> Otherwise, the Conservation of Energy principle would be violated.

There is no path for energy after waves cancel. And it's already well
known and understood that energy is conserved.

> If "energy exists only where the waves exist", how can waves exist without
> energy, as you have asserted numerous times?

There's that lie again. Evidently this is the only way for you to make
a point in a discussion.

Hi OM,

We currently have somewhere on the order of 95% to 98% excess fiber optic capacity! It is where all that money planted it, along the roads of America, just short of the homes it would serve had the technology market not collapsed 3 years ago.

The reason (or partial reason) for that collapse is called "the last mile." In terms of simple economics, that excess capacity was the simplest infrastructure addition. The problem of "the last mile" is that to connect every home (or at least enough to make marketing this bandwidth profitable) will cost vastly more than the original investment. The best short term prospects are found in the analog of a Central Office offering Wi-Fi connections to nearby RF networked communities.

Barring the planting of more fiber optic to your doorstep, there is vastly more chance of new roof mounted antennas in our future.

Actually, they're proportional to the square of the reflection
coefficients.
That's what ^2 means. Only these equations express the reflectivity of
the entire network, rather than for each surface as it would perform in
the baseness of the others like you've been doing.

> Your Rmaximum and Rminimum at any one plane have the same magnitude and
> opposite signs. Walter Maxwell said nothing remotely resembling that. He

Ah, I see. Well, you're partly right. I didn't exactly drop the other
shoe yet. When light is going from dense to less dense (looking toward
the source from the load), cos theta = 1, and
R=((r12+r23)/(1+(r11*r23)))^2,
= ((n1-n3)/(n1+n3))^2. Remember n1 is the first media and n3 is the
last media on the path. So you're right, it's not unity. (I was
"seduced" by the transmission coefficient in the forward direction.:-)
I get .64 whether I use reflection coefficients or impedances. But it's
a moot point in that direction anyway because there's nothing on the
back side of the load. The energy is has been dissipated at that point.

> > In other words, no energy is

R is zero in the forward direction - unless you disagree with Born and
Wolf.

> > The point is that any detailed energy analysis of what goes on within
> > the boundaries must be completely consistant with the steady state
> > analysis.

> There's that old "math model dictates reality" mentality again, Jim.

The math model was derived from reality, Cecil. It describes exactly
what happens. The irradiance equations, used properly with the voltages
you've been using works out perfectly without energy having to reverse
direction somewhere between the source and the match point.

> For instance: Standing waves are impossible in a single source, single
> feedline, single load system unless a forward traveling wave exists and
> a rearward traveling wave exists. Once the standing waves are calculated,
> you guys forget or deliberately ignore the existence of the cause of the
> standing waves.

The standing waves do not comprise an element in the path that energy
follows from source to load. It doesn't mean they don't "contain"
energy. It just means they don't convey energy from one place to
another. The energy they "contain" was delivered there during the
transient period. Energy is not drawn from them nor is additional
energy supplied to them.

Cecil:

Actually that "old chesnut" pits the Conservation of Energy principle against the Conservation of Charge principle. Neither principle has ever actually been "proved" and neither is an immutable law of Physics. In fact relativity theory proposes that charge [matter] and energy are interchangeable. Something Albert said about E = mc^2

If you had to pick one or the other principle which would you choose.

Heh, heh... Which of these is the strongest principal? Clearly today you like the Energy conservaton principle best...

;-)

One can mathematically "prove" that the extra E/2 energy is dissipated either as heat energy [phonons]or as radiated energy [photons] or by some combination of both by introducing some small resistance "r" and/or some small length of conductor "l" into the wires connecting the two capacitors and then showing that the energy is dissipated in the resistor r or radiated from the length of wire l as the charge is accelerated on it's trip to equalize the charge in the two capacitors.

What happens to this E/2 energy as you let r or l approach an infinitesimal r ->dr or l -> dl?

How hot does the resistor r get in degrees K? How much e^2 = kTRB Johnson noise is generated by the r?

:-)

It certainly does resolve any problems. All waves contain energy. All
waves transfer that energy when they are dissipated or radiated or when
they are destroyed by wave cancellation.

> It IS transferred there, but only during the transient period.

We know, Jim, the steady-state has supernatural powers. Too bad
the steady-state never exists in the real world. In the real world,
the transient state continues forever because of noise. Sorry about
that fact of physics.

> You've got the wrong picture in mind. Picture the oft used water pipe
> analogy. The energy source is the water spigot at one end. Water

Wave destruction is the outlet for EM wave energy just as it is for
dissipation in a resistor or radiation from an antenna. Waves CANNOT
exist without energy. When a wave is destroyed, it MUST, of necessity,
give up its energy. That wave simply has no other choice.

> You're just blithering, Cecil.

Of interest is that some of that investment was done right. My local, independent telephone company put much of their profits (over a number of years) into the ground with cable and glass. The results are that it now pays only about three pole charges (cost per year to the power company) and has very good bandwidth right where people live. Pole charges went up in cost several times once cable TV arrived. I have two telephone lines (had three when sons were at home) and DSL on one of the several wide bandwidth lines that are burred right up to the house. Takes attention to details and forward planning. The family who own the telephone company are not rich, but they live and work here.

An R of zero cannot be the cause of an R of zero. You are clearly
confusing cause and effect. Figure out what causes the R of zero
when the physical R is not zero and you will understand.

> The math model was derived from reality, Cecil. It describes exactly
> what happens.

It correctly describes the *NET* outcome which is what most people are
interested in. It does NOT describe exactly what happens. You are deluding
yourself when you draw any conclusions about physics from a net outcome.

Example: My bank balance was the same at the beginning of the month and
at the end of the month. Therefore, I had no transactions during the month.
Don't you see how crazy your illogical assertions really are?

> The standing waves do not comprise an element in the path that energy
> follows from source to load.

Of course they do, Jim. The energy that flows from the source to the
load flows on a foundation of standing waves. Otherwise, that energy
would never make it. Hint: You cannot get full source power into a
mismatched load unless standing waves exist. Standing waves can only
exist when there is a forward-traveling wave and a rearward-traveling
wave. Traveling waves cannot exist without energy.

There's a simple proof. Standing waves cause additional I^2*R losses.
The R is constant. Where is the additional I coming from?

What you are saying is that train tracks have nothing to do with the
efficiency of rail transportation since they stand still. Good Grief!

Actually, it is like asking how a railroad functions without railroad tracks. Hint: It doesn't! Standing waves are the railroad tracks that the source power uses to transfer 100% of its energy to the load. No standing waves, no 100% transfer of source energy.

Yes, that's the missing mechanism that I hope someone will supply.
We know that such a destruction of waves will not result in energy
traveling in the original direction. We know that energy cannot be
destroyed. We know that every EM wave contains energy. Therefore,
we know that the energy in the canceled waves must go somewhere.
In a transmission line, it can only go in one other direction.

> There is no path for energy after waves cancel.

Waves cannot exist without energy. These waves cease to exist at the
cancellation point. Where does the energy in the destroyed waves go?
You have asserted that waves that are about to be canceled exist without
energy, but that is obviously a violation of the laws of physics.

>>If "energy exists only where the waves exist", how can waves exist without
>>energy, as you have asserted numerous times?
>

Just to make sure I have this straight.

You calculate the average power over an integral number of cycles, and presume that there are waves containing these constant amounts of power propagating along the line, reflecting, and reversing direction when necessary to conserve energy. Then you calculate the values of these integral-cycle power waves at specific points along the line, and draw conclusions about how the energy is distributed based on these calculations.

Do I have this right? If so, how the heck can you draw conclusions about this blurry quantity of average power, which has to represent the power in an integral number of V or I cycles, at specific points along the line? And conclude that the value of the sum of a couple of these "waves" is entirely different a short distance away?

What do you do when the line is, say, the square root of two wavelengths long, so that an integral number of cycles doesn't exist anywhere along the line, even after any number of reflections?

You're still missing a couple of details. Like your description of the
splitter for example. Are you dividing wave fronts, or amplitudes? And
you haven't described this 're-combiner' at all.

> What do you think?

I think you're clue-free and hoping someone will explain it to you.
Prove me wrong. :-)

Have you read HP AN 95-1, page 16 and 17? All of those powers are
average powers. In 45 years as an engineer, I have never heard
of anyone using anything except average power, usually joules/sec,
which is virtually always indeed multiple cycles based on the
RMS value of voltage and current.

You are the only person whom I have ever known that seems to be
attracted to instantaneous power, whatever that is.

It's a mental exercise, Jim, not a bench experiment. I am pretty
ignorant of the physical equipment involved in such an experiment.
I know how to get the two re-combined waves almost in the same vector
path in which case they are not destroyed.

> I think you're clue-free and hoping someone will explain it to you.
> Prove me wrong. :-)

Yes, I'm hoping someone will explain how the energy components in two
waves that engage in total wave destruction are conserved. Your assertion
that there is no energy to conserve is ridiculous in the extreme and
violates the laws of physics.

It was eat up in heat (or radiation) in the re-combining process. You can not have a lossless recombination, if you do it violates C of E.

After much searching (Google and books) I have yet to find an answer.

Does anybody have the formulas for making a phasing coil for collinear antennas?

I would like to use coils instead of stubs, easier to make enclosures and mounting points.

TIA

N9XYP

100% of the source energy is NOT transferred to a mismatched load as
TV ghosting proves. (1-RHO^2) times the forward power is transferred
to a mismatched load. But the forward power includes an infinite
number of reflections (ghosts). There is no way to isolate the most
recently generated energy from the infinite number of reflections.

No other possibility? Why can't the energy involved in the re-combining
process simply wind up flowing in the opposite direction to the wave
cancellation? Mirrors conserve energy. Why can't wave cancellation
conserve energy the way it is described on the Melles-Griot web page?

http://www.mellesgriot.com/products/optics/oc_2_1.htm

"In the absence of absorption or scatter, the principle of conservation
of energy indicates all 'lost' reflected intensity (from the wave cancellation
process) will appear as enhanced intensity in the transmitted beam." i.e. the
'lost' reflected energy changes direction and joins the forward wave.

And you are the only person I've ever known who seems interested in tracking the power at every point along a line. Certainly the only one who does this by first averaging the power over a cycle, then concluding that it will add to or subtract from similar average values in distances much shorter than a wavelength.

You still don't understand what instantaneous power is? Consult any elementary circuit analysis textbook. I'll be glad to recommend a couple. Armed with that new knowledge, you'll be able to calculate exactly what the power is, and where the energy is going, at any point along a transmission line at any instant of time. Without it, you can't.

Don't use it much on 75. But the efficiency
cannot be all that bad, and the heat should not be
a problem. I am starting with 5 watts out of a
Yaseau FT-817 and am able to reliably check into
traffic nets I am interested in. On field day I
was answered after one or two calls, as long as
the frequency owner was two or more S units above
the background. I am heard, can pass traffic, and
if the tuner is rated for 300 watts I don't think
5, no matter what the mismatch, I am not going to
heat anything up enough to hurt it. Most people
"cook" tuners by attempting to match at full
power, rather than minimum power. Once a match is
achieved things generally work well, until you
approach maximum power tuner is rated for.

IMO the telephone companies generally seem to be poorly managed with
even poorer forward planning. Most can't even see trends which are whacking
them in the face. ALL could have had most of the ISP business early on in
the internet era instead of sitting by while AOL, Compuserve, etc etc and
hundreds of local startups took most of it. And service would have been
available to everyone everywhere at competitive pricing.

Hi Peter,

Cecil once claimed he could measure Z with a thermometer. I then
asked him the same question above and, like you, got the same vacant
answer.

He dismisses the proof of any single claim as not being relevant to
the issue, and then gusts on how the issue is proven by the claim. I
don't think we will ever see a number put side-by-side with his heat.

Hi,
I just got my general license.
I am limited on space but will be able to mount an antenna about 6 feet above my roofline. Radials are not a possibility because of structural and aesthetic issues.
I have a Icom 746Pro.
I would like a multiband compact beam or quad or vertical.
I will not be using an amplifier apart from the transceiver.
What would you recommend?
Thanks,
Paul Armes

Which makes me wonder, since he's attempting to encourage the vertical
feedline section to radiate, if he's shipping it with a voltage balun
or a current balun. He manufactures both types.

Hi all,
i discovered something strange on my 20 m dipole.
Yesterday i took a peek on my roof and the strain was about to cut a dipole arm. The inner copper wire was gone...
Now i have to rebuild half dipole and i was thinking about using a Morgain antenna instead of the dipole as i have no 40 m antenna. I found the project on Radio Rivista but i am searching for suggestions on building. I usually use plexiglass for the insulators but i think i need something lighter. Can anyone suggest how to biuld the center insulator and how to place the coax socket?

Thanks in advance

About the smallest real antenna would be a 2 element beam like a HyGain TH2,
or a Mosley(sp?) TA32JR. Either one would work with a heavy duty TV rotator.
I think Mosley also sells a 3 band rotatable dipole.

Richard Clark wrote:
"This, by the way, is not the best 6 of 10.

On a transmission line, signal is confined to the wires.

Signal can only go forward and bakward on the line.

Zo is the only voltage to current ratio propagated in either direction on the line.

If a wave on the line encounters a Z other than Zo, the wave can only deliver the volts and amps it carries.

If the mismatched Z demands more current than accompanies the volts the line carries at Zo, signal traveling down the line is not completely absorbed by the mismatched Z.

Some signal is rejected by the mismatched Z and reflected back the way it came. In the case of the current-hungry low load Z, there is excess voltage in Zo for the current Zo is able to supply. Excess volts in Zo are rejected by the load.

Counter-emf in the final inductance of Zo launches a reversed-phase (reversed direction) voltage wave.

Phase of the current in the example above is unfazed.

By analogy, phase of the current reverses in a reflection when the load impedance is greater than Zo.

Multiple phases of the same signal, either voltage or current, traveling in either direction on a transmission line are not allowed.

The phases of the same signal traveling in the same direction are simply merged. They are vectors which make a resultant.

A transmission line has forward voltage and current in-phase. If a reflection occurs, the transmission line has a reflected wave in which the voltage and current are 180-degrees out-of-phase.

The magnitude of the reflected wave is proportional to the magnitude of the mismatch.

What else do I need to know?

Best regards, Richard Harrison, KB5WZI

Has anyone put together a recent test of mobile HF antennas? I think
that I remembered something in past years called a "shoot out" or something
like that. As far as I remember though, it was as much of a test of the
installation of the antennas as the antennas themselves as different
vehicles and install methods were used. It would be nice to see on
objective comparison of the various units like the Hustler series, Ham
Stick, all the variants of the screw driver antennas, the Texas Bugcatcher,
etc. all mounted on the same platform with the same grounding system, etc.

Anyone seen such a test ?

Thanks,

Gene

I have personally compared non-resonant-whip-and-tuner, ham-stick and
hustler.
Hustler won.
Big time.
Several S-units as I recall.
Screwdrivers play well I am sure.
Resonant; lowest loss; bigggest.
comprende'?

Hi,
6 ft (2m) high above roof OK, but what total length ?
if limited to 2m high that can be suited for V/UHF, not for SSB/CW,
excepting using a mobile antenna with H-Q coil. Or excepting if you like
ragchewing in local QSO on upper HF bands and do not want work DX and
pile-ups (in SSB at leats as a good CWer can work any DX with a windom or a
short vertical.. In fact all depend of your skills in the field).

At last, do not forget that an antenna has to respect to laws of physics
whatever say advertising and marketing depts about short whips able to work
the world...

For short only verticals are short enough (low profile) to be erected
anywhere you like, sometimes with a few traps.
Most HF beams, even shortened, exceed 2-3m wide (for the boom) and display a
wingspan over 5m.
There is also magnetic loops (dia about 1m) that are very interesting, but
expensive.
In V/UHF there is no problem, or not of this kind.

So for your multibands RTX (HF, V/UHF) if there is no problem of selecting a
V/UHF antenna, in HF, due to your restricted place, the best solution should
still be the multiband dipole erected vertically (inverted V or L along the
wall or near). Many DXers work with G5RV, Windom and other W3DZZ
successfully, some with high powers.
But see the others posts dealing with wires antenna for more information.

Read this, that could also help ;-)

338. Re: A G5RV of excellent quality ?

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-04 15:56:14 UTC
From: Thierry <lombrytNOSPAM@hotmail.com>
Message-ID: <3f05a398$1_1@news.vo.lu>
Source record: 113481

Hi,

I know very well Varney's antenna (see my website,
http://www.astrosurf.com/lombry/qsl-g5rv.htm)
But I will first use it for reception, to avoid most of QRM vs a vertical
polarisation.
Up to now I have not find any antenna "better" protected against RFI than
wire antennas due to their polarization mode (I do not speak about your
neighboor's RFI at S9 but the more "transcient RFI" we usually heard using
e.g. a 6m vertical. Compared to this last the noise is reduced over 2
S-points with the wire antenna).

Later (but very soon) I will buy a TA-33-JR-N WARC beam.
So the G5RV will be mainly used as "spare" in case of problem (including
QRM) with the larger one.
But I need a good model because it can also become my usual antenna for
portable operations in place of my vertical.

So my question concern really first the quality of various models available.
I do not want a model that will break two years after installation due to
various factors (quality, stress, weather, heather, etc)

Thanks in advance for comments

339. Impendance

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-04 15:56:33 UTC
From: Michalkun <buranko2000@yahoo.com>
Message-ID: <Xns93AE64FC092E9michalkunyahoocom@128.233.192.251>
Source record: 113482

Does anyone know how to find out wire's impendance so that I can match it to appropriate balun? I want to make an randomwire antenna but I'm not sure what balun to use, since no idea about the wire's impendance. I want to use copper wire.

Hi,

Excellent advice Richard ;-)
But I hope that my local dealers can get "the best" models and up to now I don't really known what are the best models in terms of quality, resistance to stress, weather, etc.
The model I suggested on my website are based on advertisings, not measurement in the field...

Thierry

I think you need a balun. Those things are easily accessible at any
audio/video sections. I can even find them in Walmart.

Cecil, W5DXP wrote:
"---how the energy components in two waves that engage in total wave destruction are conserved."

Energy annihilation does not occur when waves coincide. The effect in a particular path may be the same as if there were cancellation. There are nulls produced in azimuths, at intersections, and wherever equal and oppositely phased signals coexist. The waves may be undetectable at these points if we are unable to separate them.

A standing wave is an example of opposites cancelling. The energy in each direction is unaffected by nulls the traveling waves make. The volts and amps are not being brought down in the same places.

When a wave is turned around by a reflection, the phase reversal of volts or amps, but not both at the same time, avoids annihilation.

Cecil suggested a contrived combination of oppositely phaseed waves of equal magnitude. I responded he might just short the outside turns connections of a center-tapped transformer to test his idea. Cecil did not respond.

When a 1/2-wave phase shift is imposed on a signal and this signal with its phase reversal is connected with the original or reference signal by direct connection, the result is a dead short. Annihilation of energy does not occur by a short-circuit connection of the oppositely phased equal signal componnents. Annihilation of the signal occurs, but it usually results in conversion of the energy into heat.

Best regards, Richard Harrison, KB5WZI

There is no way to know from this information. YOu need to give the frequecny , the length of the wire, height above ground and probably a bunch more info. YOu do not use a balun on a random wire but feed it into an antenna tuner and match it with the tuner unless the transmitter is designed for random wire such as some of the old military gear.

The random wire is mostly a make do antenna and will usually be less efficient than many other antennas. If this antenna is to be installed in a fixed location you should look at a differant type antenna. Maybe a windom type.

|
|====================================
|
|What ! Nobody feels like arguing ?

Okay, I'll take the bait.

No, 1/2 of the power doesn't get dissipated in the termination. Some
of the power in the forward travelling wave never reaches the
termination(s).

For example I have modeled a 144 MHz LaPort Rhombic that at 3
wavelengths above ground has 23 dBi gain at 5 degress elevation and
the E-plane sidelobes down > 11dB and F/B of 30 dB. With side lengths
of 3.5 and 6 lambda, and two 500 ohm terminations, the total loss in
the terminations is 2 dB.

BTW, this is probably the lowest sidelobe level I have ever seen in a
rhombic.

|
|Terminated Rhombics must be going out of fashion faster than G5RV's.
|
|Terminated Beveridges went before WW2.
|
|Have I spelt it right ?

No.

Richard Harrison wrote:
> The phases of the same signal traveling in the same direction are simply
> merged. They are vectors which make a resultant.
>
> What else do I need to know?

Exactly what happens when two out of phase components of the same
signal traveling in the same direction are merged when, e.g:

Wave 1 = 50V at zero deg and 1A at 189 deg = 50W

Wave 2 = 50V at 180 deg and 1A at zero deg = 50W

The two waves cancel, i.e. are destroyed. What happens to the
intrinsic energy in those two waves? That's the present crux
of the matter. "Those waves didn't contain any energy to start
with", insults my intelligence.

When two phasor voltages cancel, it is a well known fact that
destructive interference energy is delivered to the constructive
interference event that must exist somewhere else. It's all
explained in _Optics_, by Hecht.

It is not the wire's impedance that matters unless there are no
standing waves. If standing waves exist, the impedance depends
upon the projected impedance of the antenna, not the Z0 of the
wire.

Michalkun wrote:
"I want to use copper wire."

The reactance of a long wire is cylical and its radiation resistance depends on wire periphery as well as length. Height and surroundings also have an effect. But, an approximation is given by:

Radiation resistance = 73 + 69 log n

where n is the number of half wavelengths of the antennas.

This is from "Handbook of Electronics Calculations" by Kaufman and Seidman.

If you had one 1/2-wave of wire, any number raised to the zero power is one, so the log of (1) is zero, and the radiation resistance reduces to 73-ohms. The book actually has a graph of lengths in wavelengths versus radiation resistance and 73 ohms fits the graph at (1) half-wavelength. Offhand, that looks like the impedance of a center-fed 1/2-wavelength of wire, as well it should, because the radiation resistance is the resistance at the current maximum point for the antenna. That`s not the feedpoint for an end-fed antenna in many cases.

So, what`s the feedpoint resistance of a long wire? Often it`s quite high. The ARRL Antenna Book suggests:
"Each leg of this terminated V-beam use a 600-ohm non-inductive resistor to ground." The V-beaam has 2-lambda legs, so would have the same impedance at each wire end and the termination resistor is chosen to match the wire at its end. The wires in this section are 70 feet above ground.

Best regards, Richard Harrison, KB5WZI

I'm not talking about simple superposition. I'm talking about cancellation of waves where the waves cease to exist. And I agree that energy annihilation does not and cannot exist among EM waves.

> A standing wave is an example of opposites cancelling.

Only at certain points. The forward wave and reflected waves are unaffected by each other. There is only superposition, no cancellation except at certain points.

> I responded he might just short the outside turns

Because I thought it was a joke, Richard. The current certainly does not go to zero so your example is irrelevant to what I was talking about.

There's not much to this antenna but wire and insulators. Not much
that is breakable, unlike, say, a beam or a trapped vertical. So I'd
just go with whatever you can find. MFJ makes a g5rv for 39 dollars
US.

That kite was part of the "Gibson Girl" survival package. They are quite collectable today and sell for much more than they are worth. Visit a kite shop some time. The standard materials are fiberglass (or carbon fiber) frames and nylon sail cloth.

Just string up as much wire as you can get in there, and feed it with
a tuner. For one band, like 20-meters, put up a coax fed dipole.
It's OK to bend the ends to fit. An auto tuner works great for attic
antennas. The Icom AH-4 will tune a dipole just fine. See
http://www.hamoperator.com/ah4/ah4.htm

I have had reasonably good results using
inverted V dipoles in close proximity to my
transceiver. Cathedral ceilings prevent me
from using the full length of the attic. There was enough room for full size
dipoles only on 10, 15, and 17 meters. Loading coils and an L network allow me
to also operate on 10 and 40 meters.

Henry,
Do a search for "Flexifoil Power Kites". Not too
sure how easy they are to fly, and you'd have to want
to awful bad, but they should be able to hold up almost
anything you could tie on to them...

Cecil, W5DXP wrote:
"I`m talking about cancellation of waves where the waves cease to exist."

Fine. But, you`re talking about transmission lines, and wired circuits. The way to put together out-of-phase volts and amps is to join out-of-phase sources.

Equal volltage out-of-phase sources will produce equal out-of-phase amps, when connected. It`s about the only easy way to make opposite voltages and currents coincide.

You may have nearly lossless cables and connections, but the energy source or sources won`t be so lossless and these are likely to let their inherent smoke out.

Best regards, Richard Harrison, KB5WZI

364. help: yaesu vx-5r or kenwood th-f7????

Hello All,

I want to buy a handheld for 2, and 70cm.
I was thinking to buy a kenwood th-f7e, or
a yeasu vx-5r.
They are now in stock, the price is the same, it's
399 euro.

I heard the kenwood th-f7e has some problems.
The microphone quality of the th-f7e does not so
good (a th-f7 user told me that),a ext mic solve that problem.

S-meter reading is not correctly, weak stations
with noise are going easely to s-9 read out.

The HF bands receiving is bad, but that is easy to
explain, short antenna, and there is not enough
space for good filters.

Hf-bands is not importand for me, but we pay
for it.

I read this all on internet, and in a Radio magazine
of Holland.

There is more.

I did not find test information about the yaesu vx-5r
It has hf, but not SSB on it (it is not so importand for me!).

It has 6 meter (mode FM), the antenne is ofcourse
short for this band, and what is there to do on
FM on 50 Mhz?
I do not have expiriance on 6 meters, but I
think that it is a SSB dx-band (are there enough FM signals?)..

Does someone have expiriance with this yaesu
handheld?

Are there any problems with this trx?

Please your comments in this newsgroup.

Yes you a right "Gibson Girl" everything was yellow and the kite had a
aluminum frame that was nearly automagic..
I bought the whole setput in 1955 for less than $5.00 and now it's long
gone..
The yellow box had indentations for your legs above the knees so that one
could "easily" crank the hand generator to run the radio..
I know it had a transmitter but can't recall a receiver..
But I do recall that the kite had more "pull" than any other kite I had
tried or have ever tried for its size..
thanks for reminding me..

> Has anyone come across (or actually used) an HF
>antenna design for the attic that got reasonably good operating
>results?

My attic is about 40' X 30' with about 8' at the apex of the roof. It is 2 story so the tip of the roof is about 38' above ground. I put a big "Z" configuration feeding it at the middle of the vertical portion of the "Z". Overall wire length is 100', feed it with open wire 450 ohm line with a choke balun and tuner at the shack. My homebrew tuner can load it from 3.8 mhz. all the way to 10 meters. On 20m, 17m, and 15m it has gain in certain directions cause the pattern gets like a cloverleaf.
It interferes with phone lines, television, stereo ect. it sometimes trips my gfi circuit breaker in my kitchen. It also set of my alarm system which caused the fire dept. to visit my house. (disconnected the upstairs smoke detectors.). It can also cause my Icom to act crazy because of the closeness of the antenna to the rig. I have to back off on the power when this happens
My conclusion is this attic antenna works well, but does not work as well as if the same amout of wire was outside in the clear. It also causes much rfi that an outside antenna may or may help.

Nope, think about it, Richard. Equal out-of-phase voltage sources will produce in-phase currents, when connected. Out-of-phase currents would cancel to zero since they would oppose each other.

The zero current null in a standing wave is caused by equal out-of-phase currents. However, the voltages are in phase at a maximum. I don't see any way to hook up a circuit model of two voltages 180 degrees out of phase while the two currents are also 180 degrees out of phase. It appears to me that this special condition can only occur with EM waves in free space or transmission lines, not ordinary circuit signals.

I think maybe the answer to my question lies in particle physics. Unfortunately, I don't have any references so will need to make another trip to Texas A&M. The question seems to be: If two coherent photons exist with a 180 degree phase difference between them, what happens when these two photons are merged along an identical vector path? Seems to me, they would de-materialize in their original direction of travel (destructive interference) and re-materialize in phase traveling in the opposite direction (constructive interference).

OK, but there's still hell of a lot of power lost in a rhombic's termination.

Apart from an improvement in receiving signal-to-noise ratio, what advantage do you get for it in the wanted direction of propagation compared with other types of beam which don't need lossy terminations to obtain a unidirectional radiation pattern?

Reg.

Reportedly the antenna _will_ load up on 6 meters, if you install the
6-meter tip, but it's very inefficient. I've never actually tried to
use it.

> and what is there to do on
>FM on 50 Mhz?

Not very much. There are a number of 6-meter FM repeaters here in the
San Francisco bay area, but fewer than there were some years ago (I
understand) and there's not much activity at all.

>I do not have expiriance on 6 meters, but I
>think that it is a SSB dx-band (are there enough FM signals?)..

SSB and CW in the lower-frequency portions, FM in the upper.

>Does someone have expiriance with this yaesu
>handheld?
>
>Are there any problems with this trx?

I've had one for about a year. It's a nice little HT. I treat it
strictly as a dual-bander, having swapped the original antenna for a
more flexible 2m/440 duck from Pryme. The lithium battery carries
quite a respectable charge - I have yet to actually run it down. The
U.S. version can be programmed to monitor FM frequencies in the
222-225 MHz U.S. amateur band - nice for monitoring a few local
repeaters, although it can't transmit on those frequencies.

The VX-5 does get very warm during extended transmission at full power;
the case and the operator's hand are obviously part of the heatsink.
The SMA jack on the top has a tendency to work loose and isn't rated

for a lot of attach/detach cycles - I recommend tightening it carefully, and then installing an SMA/BNC adapter with a rubber washer or grommet at the bottom to act as a strain relief. The belt clip is untrustworthy... shop around for a replacement which actually *clips* onto your belt!

The VX-5's RF input filtering isn't great. If I hook it to an efficient full-size antenna (quarter-wave groundplane whip or magmount, roll-up or bicycle or base-station J-pole) there's quite a bit of intermodulation-related signal breakthrough from the powerful 156 MHz paging transmitters in my area. I now use an outboard anti-pager notch filter when using it with sensitive or high-gain antennas, and this solves the problem very nicely.

Audio quality seems quite good, both on transmit and receive.

The lettering on the rubber keys is reported to wear off after a few months of heavy use (a problem with many HTs these days). Yaesu makes a leather-and-plastic soft-case, which protect the keys and the display from actually being touched - I've had my VX-5 in one since I bought it and the keys show no sign of wear or fading.

There's plenty of information on the Net about the VX-5, including modifications, programming tips, and so forth.

Glenn,

How restrictive? A lot of places just put a limit as to how high off the roof it can be, like 10 -15 feet. Also, the people who wrote the restrictions have a very narrow idea of what an "antenna" is. I don't think they would recognize a wire across your back yard as an antenna.

As an aside, somebody I worked with tried to get a variancve for a tower. The neighbors objected; so, he put up a triband beam on an 8 foot tripod in the middle of the roof, and ran bright blue coax and orange rotor cable down the front of his house.

That's a heck of an attitude in an information oriented newsgroup.

Maybe if I ask my question a little differently. Here's a URL
that has a JAVA Ap illustrating interference.

http://micro.magnet.fsu.edu/primer/java/interference/waveinteractions2/

Set the amplitudes the same, the frequencies the same, and the phase
of one to zero and the other to 180 degrees. Virtually everyone has
seen a diagram like that before. The result is a straight line that
extends out to infinity. What everyone except me seems to have missed
is that straight line extending out to infinite space-time contains
a zero E-field, a zero B-field, and ExB = zero energy. What happened
to the energy in the original two waves?

Sure have! When I lived in a subdivision with restrictive covenants I used an indoor antenna with great success. I had a single-story bungalow. The antenna began at floor level in a bedroom closet, ran up into the attic, made a 90-degree turn so as to run under the roof ridge of the house and ended with a large capacity hat (full attic-width wire cage) at the gable end of the attic. I loaded all this against the water pipes and heating ducts of my house. Resonant frequency of the system turned out to be 2.8 MHz. I ran coax to a simple switched L-network which I mounted on the floor of the closet. I was able tune up this system on both 80 and 160 metres. Fine tuning was accomplished with a piece of ferrite rod taped to a stick which I slid in and out of the L-network coil! Worked as well as any low antenna on 80, and one winter, I even managed to work Europe with it--three times--on 160! So be inventive and give this--or something like this--a try. Cheers, GL es 73.

Im using an "L" shaped random wire in the attic with the end of the wire running down out of the attic into my back upper deck, down to the lower deck, down to the basement into a tuner and a good ground, but got to be realistic and keep the power down to no more than 30 watts if I want to keep the peace with my neighbors and since all I use is CW this works quite well for me

It's not obvious to me how you'd get the beams from, say, two coherent lasers, to line up exactly superimposed like that, with the exact overlayment of the two beams extending from some point to infinity. Can you explain in words or direct us to a diagram showing how that could be accomplished?

When I had my 75 meter dipole running across part of the house, I always had to tolerate RFI, or rather the family did, and I had to tolerate birdies from the XYL's TV set. zWhen I'd fire up the homebrew 4-1000 amp I used at the time the hall light, a 60 watt incandescent lamp would flicker on with voice peaks.
After I moved all antennas to a tower on another half-acre lot behind the one the house is on, all that disappeared.

My soninlaw's attic antenna installation in the Pacific Northwest worked out OK but had the same sort of RFI problems you describe, at any power level above 25 watts or so. I don't think that is a situation that lends itself well to a good resolution where you can run normal power levels and not have the usual set of problems with it.

Peter, Peter

Its "I'm pen dance" - said one pen to another while twisting waves around the undeterminated cooper wire.
The other pen said: "Just bring the wire through the window, hook it to the antenna tuner also called matcher box, twist the knobs until you have no Cecil reflections and you no need no stinkin' balun or baloney."
The #1 pen said: "What a bright idea" and they continued in the pen dance untill they lost all the energy in the die electric mediuma.
Now you know the rest of the story.

Cecil, W5DXP wrote:
"Set the amplitudes the same, the frequencies the same, and the phase of one to zero and the other to 180 degrees."

From the 1955 edition of Terman page 1:
"The essential properties of a radio wave are the frequency, intensity, direction of travel, and plane of polarization."

Cecil`s question seems to be, suppose we have two sources of identical waves which coincide except one source is 180-degrees out-of-phase with the other.

We can likely approximate the two sources with two antenna elements driven out-of-phase, or they could be driven so that the space and phase between them combine to produce a null in a certain direction or directions.

There are countless such examples. Several are given on page 8-8 of the 19th edition of the ARRL Antenna Book.

Gain in the antenna containing the directional pattern with nulls results from the same amount of power in the directional antenna as in the non-directional antenna. The power which would have gone into the nulls goes instead into the rest of the pattern. That qualifies as a "change in direction" but I doubt that is what Cecil meant.

Cecil wants to talk about light waves in a thin optical film and to try to relate that to shortwaves on a transmission line.

Cecil seems to have trouble seeing that out-of-phase sources produce out-of-phase currents in a load. You can be sure that if the load is a resistor, that is exactly what happens. Out-of-phase sources produce out-of-phase currents in a common resistor.

The condition proposed for a wired load is a short-circuit, and we know the outcome of a wired short-circuit.

Best regards, Richard Harrison, KB5WZI

I guess clarification is needed on what the RF ground is for..
Many hams interchange RF ground for a counterpoise for
vertical or end feed antenna.

|==============================
|
|OK, but there's still hell of a lot of power lost in a rhombic's
|termination.
|
|Apart from an improvement in receiving signal-to-noise ratio, what advantage
|do you get for it in the wanted direction of propagation compared with other
|types of beam which don't need lossy terminations to obtain a unidirectional
|radiation pattern?

I developed the model of the antenna described above while dreaming
about a simple, low cost EME antenna that would be useful at moon rise
at my location.

Clearly, it would be of limited usefulness and no better than a (very)
long Yagi.

I am not a proponent of rhombics, in fact the plethora of minor lobes
in most designs is awful. Also, the wide bandwidth properties are an
illusion if the pattern is a consideration.

I spent several hours optimizing the design and if minor lobes are a
consideration (for EME they are), it is actually quite critical. That
said, 23 dB is a lot of gain, even throwing away 37% of the power.

> Anyone seen such a test ?

They have had a few, but they kind of fizzled out. But as far as which
is best, they have tested enough to know that. Also, like you say, the
car or truck used, the height and location of the mount are important,
and also what bands are used.
Naturally, the most loss is on the lower bands, so 80m is usually used
as the band tested. On the higher bands, you can use a lesser antenna
with good results , where as on the low bands this may not be
possible.
As far as the ranking, usually the bugcatcher is considered king of
the hill. If a large capacity hat is used, no contest.
The coil location is more likely to be higher than most screwdrivers,
and it's easy to have an efficient coil.
The screwdrivers are generally a close second.
The hustler would be a fairly distant third. Hustlers have a lossy
coil for it's size. The big "super" ones, worse than the small ones.
The standard hamstick is lower still. How bad depends on the length of
the stinger on top.
An unloaded whip tuned with a tuner is about the worst.
Of course, there are exceptions...You can modify antennas to improve
them, and the price don't mean doodley as to the performance. Also, a
hamstick is fairly lame on 80m, but works quite well on the higher
bands as long as the stinger is not too short.
My antenna cost me nothing and is based from an old 20m hamstick. I
made a new appx 3 inch dia coil which has taps for all bands. It
weighs about the same as an average fishing rod and reel. It's 10 ft
total and center loaded. I'll take on most any bugcatcher or
screwdriver. It's equal to a 10 ft center loaded bugcatcher with a 3
inch coil. I also have a 3 ft extender mast which will increase it to
13 ft tall, and the coil 8 ft off the base. I can dog the screwdrivers
with low mounted coils on 80 and 40. I have a hustler coil and stinger
which I have tried on solid masts, on the same mount I use my normal
antenna on. My "plastic bugcatcher" mangled the hustler. No contest at

all. My homebrew coil, even formed on thin 3 inch plastic tube, is far superior to the hustler coil. I think very close to a normal bugcatcher coil with an open form.
I wish they had more "shootouts". That might be fun to have at the Belton TX hamfests....:/ Thats about the only hamfest I go to. And I miss half of those...

I finally have a picture of my mobile antenna taken at last weekends yard day.
http://web.wt.net/~nm5k/fd2003-1.jpg
It's to the left mounted on the side of my old "safari wagon".
It's not the best pix, but you can see what it looks like. It's in the standard 10 ft tall "driving" mode in that picture. The base is over 4 ft off the ground, mounted on the left side of the utility box. The coil is about 5.5 ft above the base, and the stinger is 5 ft. With the extender mast, the coil is over 8 ft off the base. Thats as tall as some peoples whole antenna...Of course, I don't usually drive with it that tall. How you see it in the pix is how I use it when driving. I have a quick disconnect, and you can take the antenna off in a second. It's very light and flexible. I can slap trees and it's no biggie. We were setting up my beam and tower that I hauled on that motorcycle trailer.
You can see other pix at
http://bvarc.freeshell.org/images/FD2003/index.html
They put us on TV this year. But me from a ways back ...:/ I told the cameraman I was too damn ugly to be on TV. So they showed me way off in the distance working on my beam and interviewed others closer up. One of our guys mentioned the "homeland security" aspect of the deal. They ate that up. I think thats why they put us on this year. Usually, they tape, but don't show on the air if there is no need for some "filler" on the newscast. MK

A little simpler equation than the one Roy gave if you know the Gain
(here it is not in dB, so for 0dB the Gain is 1) is from reciprocity:

Matched Cross Section = Gain*lamdba^2/(4*pi)

Assuming the wave matches the polarization of the antenna, the matched
received power is the incident Power/Area times the cross section.

P = Gain*lambda^2/(4*pi)*(Incident Power/area)

A plane wave with rms electric field of E_rms has an incident
Power/Area in SI units of E_rms^2/(mu_0 c), where c is the speed of
light and mu_0 is the permeability of vacuum 4*pi*10^(-7) Newtons/Amperes^2.

Plugging in, using a numerical factor of 3*10^8 m/s for c, mu_0*c has
a numerical value of 120*pi, and solving for E_rms gives

Erms = (1/lambda)*sqrt(480*pi^2*P/Gain)

Comparing with the equation Roy posted, we see that the G factor in
that equation is just Gain/2 for a thin wire, and he verifies that for
the half wave dipole where Gain=1.64 and G is .82.

73 Kevin w9cf

In rec.radio.amateur.antenna Roy Lewallen <w7el@eznec.com> wrote:

: The one critical piece of missing information is the frequency or
: wavelength. Manipulating some equations from King, Mimno, and Wing's
: _Transmission Lines, Antennas, and Waveguides_, the field necessary to
: generate a particular power P in a load connected to a receiving antenna is

: Erms = (1/WL) * sqrt((240*pi^2*P)/G)

: where Erms is the RMS field in V/m, WL is the wavelength in meters, and
: G is a complex function calculated and graphed in the text. (It's f in
: the text; I used G to avoid confusion with frequency.) This is for an
: infinitely thin antenna parallel to the impinging field, terminated with
: the complex conjugate of its feepoint impedance. For a half wave dipole,
: G is about 0.82. But a half wave dipole has a gain of 1.64 relative to
: an antenna with 0 dBi gain. So a field sqrt(1.64) = 1.28 times greater
: would be required for the 0 dBi antenna. Plugging in the numbers,

: Erms = 119.2/WL volts per meter.

: It should be possible to confirm this with NEC-2 by modeling a
: terminated dipole with an applied plane wave source. (EZNEC doesn't have
: the capability to model the plane wave source.)

The UHF preamp dies if you wear two radios on the same side of your
betl, or if you have two antennae with small distance installed on top
of your roof, one connected to a high power transceiver and the other
one to the F7. Kenwood knows about the problem, they should write this
in the manual...

The beam from *one* coherent laser is split into two parts and then re-
combined out of phase in a typical inferometer.

I don't know how it is possible to perfectly collimate two light waves in
free space because I'm fairly ignorant of interferometer hardware. But I
submit to you that collimation of two RF waves within the physical boundaries
of a coaxial transmission line is impossible to avoid. In a transmission line,
all one would have to do is generate the two wave components.

Seems to me, the two wave components happen to be s11*a1 and s12*a2 in the
b1 s-parameter equation. That's how b1 gets to zero, through 100% destructive
interference. Page 16 & 17 of HP's AN 95-1 Application Note on s-parameters
explains the power relationships of all the quantities in the equations and
incidentally, |s11|^2 is the power reflection coefficient looking into the
physical impedance discontinuity from the source side.

Cecil:

In HP's applicaton note they refer to the magnitude squared of the
reflection coefficient which is *not* the reflection coefficient squared.

i.e. |S11|^2 is definitely not S11^2.

|S11|^2 = S11 x S11* ; i.e. S11 times its' complex conjugate.

Hello All,

Why does kenwood not made a good protection
in the RX front end section after so many years
expiriance?
It must have the same problem when people are in
the fields with contest (hi power).
I do not like the idea to always renember that the th-
f7 is sensetive for that.
It's intresting, I think to download a schematic of
this kenwood handheld by www.mods.dk

But I think to choose for the yaesu VX-5 or the new
VX-7.

What is the difference between them?

Does the VX-7 have something bad, or is het
100% okay?

Cor

Who said it was? That's why I put magnitude marks around s11 above.
As you probably know, RHO is often used without a gamma angle so
it is common to see RHO^2 as a power reflection coefficient. If
it will make you feel better, I'll try to remember to put magnitude
marks around |RHO|^2 from now on.

From the IEEE Dictionary: "reflection coefficient - ... the ratio
of some quantity associated with the reflected wave to the corresponding
quantity in the incident wave. Note: The reflection coefficient may
be different for different associated quantities, and the chosen
quantity must be specified. ... Examples of other quantities are
POWER and current." emphasis mine.

So your original assertion:

> Additionally there is no such thing as a "power reflection coefficient"
> as you have called it.

is proven false by the IEEE Dictionary. Don't you just hate it when
that happens? :-)

411. Ground plane and dipole antenna construction

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-05 15:34:23 UTC
From: captainvideo462002@yahoo.com
Message-ID: <d980bc2c.0307050734.4bce8759@posting.google.com>
Source record: 113454

I operate a 110 Watt FM low band station for business use on 43.00 MHZ. When we
installed the system 12 years ago I cut a quarter wave dipole made from #12 solid bare copper wire, fed it with RG8U and suspended it from a wooden mast off my chimney at an angle of approximately 30 degrees between two plastic insulators. Having had no SWR meter at the time I simply cut it to its
theoroetical length and hoped for the best. It was only intended to be a temporary arrangement but it has worked so well through the years, affording us the coverage we needed that there was never any reason to go much further. Recently, we have expanded our operating territory and would really appreciate a little more coverage. So with this in mind, I borrowed an MFJ SWR/freq. meter from a friend and took a look at at my antenna at the transmitter end. According to it, the length seemed to be a bit too long, (which surprised me since I know my original calculations were correct), so I trimmed it, (a good 6 or 7 inches) to obtain an SWR of 1:1.
At the same time I constructed a second, ground plane antenna. This time my coax is Mil spec RG214U which terminates in a PL259 at the antenna end. This then screws onto a female chassis mount connector and is mounted inside a
PVC pipe. There is a #12 insulated copper wire cut to quarter wavelength which runs up inside the pipe as the active element. The pipe is capped off with RTV. Coming off the female connector, and through the pipe are 4 ground radials which are cut to .95 quarter wavelength. These are again connected to plastic insulators and tied off and droop at an angle of approximately 45 degrees, which according to the ARRL Antenna Book, provides a closer match for a vertical antenna to a 50 ohm line. When I performed the SWR check on this newly constucted antenna connected to the transmission line at the transmitter end, It seemed to resonate at around 39MHZ. which was certainly far from what I had expected. I did trim it accordingly, trying to be certain to leave the ground radials at 95 percent of the finished center conductor length, and eventually got the SWR as measured at the transmitter end down once again to very near 1:1. So in theory this should have been it. Or so I thought.....
Now both antennas go through a coaxial switch and feed my base station. And
although they both work, the old crappy dipole still seems to perform better than the ground plane. However I should add that since trimming the dipole I'm now questioning if its still as good as it was before I messed with it. I have tested both antennas between a distant mobile at different locations on more than one occaision and I seem to always find that switching to the

dipole always seems better. The dipole hangs from a wooden mast not quite vertical but as I said at a slight angle. Both antennas are at the same height and on the same roof about 10 feet apart. It seemed to me that no matter what, a good SWR reading at the transmitter end would mean maximum power transfer to the load, (antenna), or so I thought.
Recently I spoke with a friend who's been in the two way businees for years. I told him about my situation and he said that its very possible that my original by the book lengths were probably correct. He advised me to recut the antennas to theoretical length, and tune for best SWR first right at the antennas. At that point he suggested connect the transmission line and see what it looks like. Depending on the transmission line's length, he said that the line could sometimes be resonating on the operating freq. The SWR meter would see the line possibly resonant at the operating freq, and so it and the combination of an incorrect length antenna would fool it into thinking, (for want of a better
term), that everything is OK when of course its not? I do understand the concept but I'm not exactly certain of the correct procedure to use to properly address this. He suggested that I measure the lengths of my lines and confirm that neither one is cut to some multiple of my operating frequency. That would be nice to be able to do however, but since both are now run through the house and fished through the walls this is now impossible.
How does this sound: I recut both my antennas to theoretical lengths and then check for proper SWR using a two foot piece of coax right at each antenna. At that point I can tweak the element's lengths for optimum. When this is finished, hopefully I'll have two properly cut antennas for my operating frequency. Now he says that as long as my transmission line is not inadvertantly cut so as to fall as some multiple of my operating wavelength, and become the resonant element, I should be all set. But even better yet, at this point, if I terminate the antenna end of my transmission line with a dummy load and check its SWR, and as long as my feed line is flat at the operating freq then I should be able to connect it to the antenna and not affect my previous SWR measurement? In a perfect world then everything should be fine? Does this sound like a plan, or if anyone might have anything else to add, I'd really appreciate it.
I appologize for the long windedness of this post but I wanted to provide as much information as possible.
Thanks very much for reading it and for any additional help you may be able to offer. Lenny Stein.

For what's its worth, some QST articles in the 1970's talked about
the power reflection coefficient, RHO^2.

A while back I was in that situation and for a year or so ran a multi-band dipole - several dipoles with a common feedpoint. I also used a 'slinky' dipole with reasonable results on 40m. Although it could be loaded up on 80m results were not very good on that band. The only time I had a problem was on 15m - running 100W - which would result in total loss of all sound on the stereo on the floor below; turned out the speaker leads were resonant near 15M and aligned with the antenna; changed the speaker positions to move the resonance and the problem was resolved.

Let's stop right there so those of us trying to understand won't get confused.

You posed as an example of your question the web site showing interference between two light waves, "extending out to infinity", and wondering where the energy went. Good question. But it's not a good question if there's no way this situation could ever occur.

Let's do one thing at a time, ok? Before going on to transmission lines, scattering parameters, and whatever, let's see if the example you gave is even possible to accomplish.

Some of the participants in this thread are apparently familiar with optics. Hopefully, one of them can answer the following: Is it indeed possible to perfectly collimate two light waves, traveling in the same direction, in free space -- either from two separate sources or from a single source -- so that the two travel together "to infinity"? And do it without something happening like a reflection back from the point at which the two out of phase beams are combined?

I use a homebrew 6-band trap dipole for 10, 15, 20, 30, 40, and 80
meters. The series traps considerably shorten the antenna allowing it
to fit in a typical attic. For details see:

http://users.tellurian.com/jdegood/coaxtrap/

Lenny,

Some comments here.

When you cut the antenna by book, what book? The accepted length for a half wave dipole in feet is 468/F(MHz). That is 10.9 feet, 5.45 feet on each side. You said quarter wave - didn't mean that, did you? Your vertical radiator, and each of the ground plane wires should also be 5.45 feet.

RG213 is mil spec all right, WW2 mil. You might pick up a couple of db by switching to LMR400 coax. (same size)

I assume the mobile units use vertical antennas. Any horizontal components your antenna puts out will be attenuated by as much as 20 db relative to the vertical.

At 10 feet separation, it is quite possible that there is interaction between the antennas. Also, when you added the switch box, did you reverse the phase of the original antenna? I don't think there is any theory to back this up, but I would connect the center conductor of the coax to the high half of the dipole.

By conventional wisdom, the vertical should work better with vertical mobile units. You might try getting it higher up. You could use the radials as guys, with insulators at 5.45 feet. Forget the PVC.

The impedance of a dipole is about 70 Ohms, and the GP vertcal should be about 50 Ohms with the drooping radials; so, at resonance your dipole SWR would be about 1.5:1, not 1:1. Trimming it closer to 1 should not hurt anything though. All that PVC pipe is probably lowering the resonance of the GP.

Cecil:

I beg to differ from the IEEE's dictionary.

"The Reflection Coefficient" rho is complex not real.

rho= (R - Z)/(R + Z) is complex since the reference impedance R(p) is sometimes complex and most certainly the load impedance Z(p) is complex in the general case.

In fact in the general case considering the complex frequency p = s + jw, [p is Heaviside's operator or the LaPlace Transform frequency variable.] R(p), Z(p) and rho(p) are all complex functions of a complex variable.

For real sinusoidal angular [radian] frequencies w = 2*pi*f [Where f is in Hz] the reflection coefficient rho may be expressed as:

rho(jw) = [R(jw) - Z(jw)]/[R(jw) + Z(jw)] = B(jw)/A(jw)

Where A(jw) and B(jw) are the Fourier Transforms of the incident and reflected "voltage waves".

Now taking the logarithm of the complex rho we have the usual definitions:

ln[rho(jw)] = ln|rho(jw)| + j arctan[Im{rho(jw)}/Re{rho(jw)}] = Ae(w) + jphie(w):

Where Ae(w) is the "echo attenuation in Np, often called the return loss, and phie(w) is the echo phase often called the return phase.

A quantity that might be of interest to *you*, and which I believe you would have fun exploring, is the trigonometry free derivative of the echo phase with respect to frequency, called the "echo group delay" tgre(w):

tgre(w) = -d [phie(w)]/dw

tgre(jw) is always real [not complex] and has units of seconds and is called the "echo delay" it is actually the "group delay" of the echo returned in B when rho is driven by A at the discontinuity where R meets Z.

Wonder what tgre(jw) looks like?

Interesting, no?

Point is, it can occur in a transmission line which is what this
newsgroup is about. Since most of this information seems to be
contained in the field of optics, I'm asking a "what if" question.
Einstein asked a lot of "what if" questions.

Point is, it is possible to conceptualize it and it can actually occur in
a transmission line where the coax does the necessary collimating.

Peter Brackett wrote:
> I beg to differ from the IEEE's dictionary.

Exactly what do you differ with them about? You didn't re-quote
the definition so I have no idea what you are talking about.

> "The Reflection Coefficient" rho is complex not real.

The reflection coefficient, rho, is often close enough to real
to be considered real. The power reflection coefficient is not
complex. The power reflection coefficient is |RHO|^2.

> rho= (R - Z)/(R + Z) is complex since the reference impedance R(p) is
> sometimes complex and most certainly the load impedance Z(p) is complex in
> the general case.

"Sometimes complex" but not always. The two characteristic impedances at
an impedance discontinuity between two transmission lines are usually
considered close enough to real to be considered real. It is indeed real
if the transmission lines are lossless, a common assumption. That greatly
simplifies the calculations and the power reflection coefficient becomes
very useful.

As you probably know, a lossless analysis is often sufficient for the
purpose. I analyze all my open-wire transmission lines as lossless
which is close enough for engineering accuracy. You must be a physicist. :-)

As far as I can determine, nothing in your posting disagreed with the
definition of "reflection coefficient" that I posted from the IEEE
Dictionary. Essentially all the IEEE definition said was that a voltage
reflection coefficient exists, a current reflection coefficient exists,
and a power reflection coefficient exists. Have another Mint Julep and
please chill out.

I'm planning on putting up a 130' inverted V fed with 450 ohm ladder line. At the radio end will be my trusty Yaesu FT-817 feeding to a LDG Z11 auto tuner. The tuners output will be coupled to the ladder line with a 4:1 balun. So far, so good.

Here's the sticking point: Isn't a 4:1 balun a mismatch for 450 ohm ladder line? I'm no expert (haven't hit the books since I got my ticket) but a 4:1 balun running on coax (50x4=200) seems a poor match for 450 ohm ladder line.......

Does it matter? Why does nobody make 8:1 baluns?

oh, so you are aloud to make simplifying assumptions when it is convenient
for you because you don't want to use the complex power and complex
reflection coefficient... but you won't let us make the steady state
assumptions that are much more widely used and accepted?!?!?!

the tuner should be able to tune that so the radio is happy. if the
impedance is out of range of the tuner then maybe you could try a higher
ratio balun.

I hope you mean a 1/2 wave dipole. You did not state how long the coax is. If very long then the swr will be way lower than the antenna actually is. If a halfwave antenna and 50 ohm coax you should see a swr of 1.5 to 1. The 1/2 wave antenna is 70 ohms if not too close to anything. YOur mistake is using the MFJ stuff without understanding what is going on and changing a working system. YOu can cut the antenna to the length where the swr is the lowest at the frequency you are usiing. If cutting an antenna for swr, sweep a few khz to mhz to each side of the desired frequency.

Hi Ken, If you are to use this very fine antenna on all bands, don't try to impedance match with a 4:1 balun. The problem is the antenna almost never presents a 450 ohm load to the tuner, so the 4:1 ratio can be anything. You will do the impedance matching with the auto tuner, the only reason you should a require a balun is for feedline radiation. Feedline radiation can cause a number of problems, or it can be no problem at all.
Your auto tuner should work if you run the 450 ohm line directly to it. If you feel you need a balun, there are several 1:1 choices that work quite well.

Hi Dave, Why should he be trying to impedance match with a balun, especially if he wants to operate on different bands, as most Hams do with a 130' dipole fed with ladder line.
The 4:1 balun or any other ratio other than 1:1 doesn't make much sense. A 130' dipole fed with ladder line, 1:1 balun and an auto tuner will work many bands. If it won't work your favorite band change the feedline a couple of feet, and then it will.

>
>72's de Ken KG0WX
>

Ken,

The balun impedance ratio is not particularly important on the system you describe. The reason being is that the impedance presented at the balun in seldom ever 450 Ohms. For example, here is the results of NEC model run for a 130 foot dipole mounted 50 feet high over average ground, fed with 65 feet of 450-Ohm window line.

Impedance at the antenna fed point.

Freq (MHz) Z Angle
1.900 1,078.42 -89.63ï¿½
3.750 95.03 37.13ï¿½
7.150 4,575.23 20.04ï¿½
10.125 550.00 -79.15ï¿½
14.175 2,522.73 52.01ï¿½
18.114 324.90 -67.39ï¿½
21.225 1,436.25 58.31ï¿½
24.930 731.19 71.76ï¿½

Impedance at transmitter's end of the transmission line.

1.900 79.69 -87.94ï¿½
3.750 734.64 -68.39ï¿½
7.150 668.20 -77.93ï¿½
10.125 1,535.40 68.10ï¿½
14.175 269.59 -74.96ï¿½

18.114 260.60 -63.80ï¿½
21.225 83.79 -27.45ï¿½
24.930 238.54 -68.61ï¿½
29.000 530.03 69.29ï¿½

As you can see, the balun never sees an impedance of 450-Ohms. In fact, chances of the transmitter's end of the transmission line ever presenting a 450-Ohm (R450 +j0) impedance is right up there with wining the Readers Digest sweepstakes. <g>

The impedeance will vary considerably over the 80-10 meter range. the 4 to
1 enables a best compromise for it all.

i'm assuming from the description that his tuner doesn't have a balanced input so to feed it properly he would need some kind of balun. the exact ratio of the balun doesn't really matter as long as it gets something in the range that the tuner will handle.

438. Re: tower grounding

'BB',
40 feet of wire and a ground rod won't make a very good
electrical ground for your tower. But it's a good start.
The ground rod connected to your tower may satisfy your local
electrical code, but it's a 'p' poor ground for lightning
safety considerations. The 40 feet of wire you already have
plus a couple hundred feet more, laid out as radials (then
connected to the tower) will work much 'better'.
If the tower is metal and the mast (or antenna) is well
connected to the tower, there's no need to run a seperate
ground wire up the tower. It probably won't hurt a thing
but it also isn't helping much either.
Just for 'grins', go take a look at a copy of the National
Electrical Codes (NEC) at your local library. Lots of good
and interesting information in it...
'Doc

Put up a 6 foot pole. Get some #26-guage black insulated wire from The
Wireman (see his web site). Make an inverted-v dipole. No one will see
the wire, just the pole. Feed the dipole with 300 ohm Radio Shack
clear-plastic twinlead. Tune the whole thing with your built-in tuner,
or an external tuner, if needed.

Put a little 6/2 meter beam on the pole, and brag to your neighbors
about your great "tv reception."

As an all HF band antenna, your feedline will always carry
a relatively high SWR. Therefore, you will *NEVER* see that
Z0=450 ohms. In my opinion, you would be better off with
a 1:1 choke, like a W2DU balun.

I've already said that I am not familiar enough with interferometer
hardware to know the answer to that question. But the point is that
even if it cannot happen with light in free space, it can happen with
RF in a coaxial transmission line where collimation is forced on the
waves by the physical configuration. In fact, not being able to
accomplish that feat with light in free space may be the reason it is
not understood for transmission lines.

You are perfectly free to use whatever simplifying assumptions you choose.
All I am after is the physics laws underlying those simplified assumptions.
I'm not trying to change anything. I am trying to understand something.
I said this is *NOT* a new and different system of analysis. The only
purpose of my postings are to try to track the energy components
around an impedance discontinuity in a transmission line. What is wrong
with me being curious about that?

If the SWR is 20:1, the impedance presented to the tuner might be
450/20 = 22.5 ohms. A 4:1 balun will try to bring that down to
5.6 ohms, not a good match. A higher ratio balun would be an even
worse match. The impedance can be out of range of the tuner on
the *low* end.

Well, Gene,

Here's my comment. Cecil used to regularly post the results of various 75 meter mobile antenna "shootouts" until I posted the following comment:

These shootouts are worthless for the following reason. The shootouts measure ground wave signal level. Most useful 75 meter communication (i. e. over a dozen miles or so) is by way of ionospheric reflection (of high angle radiation), and the high angle radiation is not well correlated to the low angle which produces ground wave for these small aperture radiators.

So, until someone comes up with a practical way to fully characterize high angle radiation from typical mobile antennas, there is no well documented answer to your question, at least for 75 and 40 meters. For 20 meters and up, there isn't a great deal of difference unless you choose something really lossy.

Message-ID: <vgf7fdaiaf73aa@corp.supernews.com>
Source record: 113391

That's interesting. In modeling, I've found that for antennas with about the same vertical pattern (which is the case for the "shootout" antennas"), the ground wave and sky wave are very well correlated. The difference between antennas (I believe) is primarily the efficiency. And when I model a single antenna and alter the efficiency by changing the ground or wire loss, the ground and sky waves change virtually exactly the same amount, as you'd expect.

Of course, the correlation would be poor between two antennas having different polarization, say one horizontal and the other vertical. But I don't think that's the case with typical "shootout" antennas -- even considering that the vehicle radiates nearly as strongly as the "antenna".

Do you have an example of two short vertical antennas for which the correlation between ground and sky wave is poor? I'd like to see if I can spot this poor correlation in model results.

Roy Lewallen, W7EL

Hello,

I can't see why anyone would want to complain about that posting - it IS a genuine offer. I contacted the RSGB and they confirmed it is featured in the RADCOM magazine.

Are you just annoyed that you had to pay more to join or something, or maybe you can't get a licence!

Good question. They do not see this as a real problem, and I was told
by a Kenwood representative at a hamfest that wearing two handhelds on
a belt is almost misuse :(

And another problem is, many users even do not know that their
receiver is damaged, because they do not feel the difference between
0.2 and 0.6 uV at 12dB SINAD, and/or they do not have another radio to
compare.

> with me being curious about that?

if i am free to use a set of well defined and accepted assumptions that
leads to steady state solutions why do you attack them? the sinusoidal
steady state conditions are well understood by engineers and hams world wide
and provide accurate answers to transmission line problems. if you go back
to the formulas they are derived from in any of the many texts that have
been referenced you can see exactly where the currents and voltages come
from and how reflections work from the most basic boundry condition analysis
(and from then derive powers if you really feel the need). starting from a
derived value like power or energy will never give you a complete picture
because you can't see how the more fundamental values of voltage, current, E
and B interact.

> >I am contemplating purchasing a High Sierra screwdriver antenna to mount on
> >the rear of a motorhome. Does anyone have any experience with this antenna?

Yes, do buy the High Sierra. They don't use fingerstock and they have
an all metal custom motor. I had the Tarhell and the Hi Q, both were
pretty bad. They had used motors. The whip screwed into aluminum;
really! both stripped out after a few months. Machining on both
looked pretty poor.

On my High Sierra, the whip screws into brass. The motor is quiet.
It is a snap to tune. Machining is done by a CNC. Parts are
stainless. It is just top notch all the way around. You won't be
sorry. It even costs less than the other two.

news:<3F030933.4090506@rochester.rr.com>...
> Can anyone explain why it's called a 'screwdriver' antenna

I can. The idea has been around since the early 1950's. There is a patent in the early 1950's. There is also another patent in the early 1970's. Some companies came and went in the 1960's and 1970's. For example, there was the Autenna, MasterMobile and the Swantenna. All were motorized and tuned remotely.

High Sierra and TJ antennas began to advertise and manufacturer the antenna design using a Skil battery operated screwdriver in 1993. While TJ is pretty much gone from the picture, High Sierra still advertises monthly with quarter page ads in QST and CQ. It is fair to say that High Sierra really made the idea popular through a lot of advertising and going to conventions across the country over the last decade.

The motor was changed about 4 years ago from the screwdriver to a commercially made motor. The current production uses an all metal, custom, gearhead motor. But, the idea of a 'screwdriver antenna' has stuck.

460. Good attic antenna

What you view as an attack upon the steady-state model is really an
attack upon the concepts of people who religiously believe that the
steady-state model has power and control over reality.

TRANSMISSION LINES WOULD WORK EXACTLY THE SAME WAY IN REALITY IF THE
STEADY-STATE MODEL HAD NEVER EXISTED! Oh, no! Now I have let your most
closely guarded secret out of the bag and turned your sacred cow into
hamburger. :-)

yep they sure would, but without the sinusoidal steady state solutions we
would not have smith charts, thumbrules about impedance transformations in
1/4 and 1/2 wavelength stubs, and it would take a phd to calculate a
matching network for a simple antenna. the power of the steady state
approach is that it gives us accurate answers to a wide range of common
problems that can be verified with simple measurements.

Mineral oil from the drug store works. That's what I used, but it gets expensive buying all those half-pints. MFJ sells a gallon of transformer oil -- probably cheaper, but might be expensive to ship.

Mark-

The RM-75 comes with both a coil and a whip. Mine is NOT six feet long. I think four feet is closer, since it easily fits inthe trunk of my car. If your friend's does not have the whip, he may be able to fit a stainless whip from some other source. Perhaps it would be helpful to trim a piece of stiff wire for best SWR, to determine how long a whip is needed. I believe Hustler will sell you a new whip for less than the price of a new RM-75.

Mine works fairly well on a triple-magnet mount on my Toyota. It is a little worse than 1:1, and has a very narrow bandwidth, about twenty KHz as I recall.

Rob, on the grounds that anything will work, just hang up the longest length of plastic insulated wire in the form of an open ended loop which will fit nicely into your attic. Keep the ends 2 or 3 metres apart.

Use the domestic hot+cold plumbing system as a ground.

It will be hard to improve on such a simple arrangement unless you confine yourself just to one band.

We'll be listening out for you with similar set-ups.

Reg, G4FGQ

Why would Cecil listen to Crazy George, at least in this case?

The shootouts are not worthless. Vertical antenna of 1/4 wavelength or less will produce the same pattern (OK car can participate as a nonhomogenious "radial") and measurements are indicative of the systems performance. See W7EL comments.
The true evaluation of mobile antennas should be done on the same car, same mount and same setup.

One interesting finding by K9UWA is that Q or quality of loading coil (wire size) does not have significant impact on efficiency of mobile antenna. That's measured and "reasoned" by W8JI.

Cecil, W5DXP wrote:
"IMO, a wave carries the same amount of energy back from a mismatched load whether it is dissipated, radiated, or cancelled."

Energy is the ability to do work. Potential energy may be inherent in a ball at the top of an incline. Kinetic energy is inherent in the ball rolling down the incline. A pendulum is constantly exchanging potential energy for kinetic energy and vice versa.

A wave is a physical activity that rises and falls, or advances and retreats periodically as it travels through a medium.

A radio wave ia a physical, periodic, activity of energy traveling through a medium (which may be a complete vacuum) and which requires no substance for propagation, only the energy fields. These fields exhibit real force such as the magnetism which turns a motor or the electric attraction of plate volts on electrons in a vacuum tube.

A radio wave conveys energy in a vacuum or guided by conductors. Either way, a radio wave is energy in motion.

A radio wave may be conveyed, redirected, or absorbed.

To cancel is to annul, to bring to zero, and to invalidate for reuse.

A cancelled radio wave is neither conveyed nor redirected. It must then, be absorbed.

Best regards, Richard Harrison, KB5WZI

How did you figure the transmitter end impedances without knowing the length of his feedline.

Maybe so. But, many more people simply believe there are models which can accurately predict steady-state behavior when given the right data and properly manipulated.

Ive tried this setup with 4:1 and 1:1 BALUNS, seems to always be a band that doesnt load up that well. Rig up something so you can add in a 1/4 wavelength of transmission line on the band that gives trouble. Or better yet use two antennas designed so that the hard to feed points on one antenna are the easy ones on the other.

Whats the best way to attach a solder lug to aluminum tubing. I dont want ot pop-rivet it on because that is too hard to get off and sheet metal screwa always come loose. I was thinking about putting in a pop rivet then drill and tap the rivet.

Well, I sorta disagree for pretty much the same reasons as Roy. The
patterns , unless distorted by the car body, will not change very much
at all between the various height short vertical antennas. All should
have about the same exact pattern, with differences in efficiency. So
if you increase the FS at 5 degrees, you should have also increased FS
at 35 degrees if increased efficiency was the reason for the increase.
I think in most all cases, the high angle radiation does correlate to
the low angle radiation quite closely.
>
> So, until someone comes up with a practical way to fully characterize high

> answer to your question, at least for 75 and 40 meters. For 20 meters and
> up, there isn't a great deal of difference unless you choose something
> really lossy.

Well, being most all mobile verticals are not really well suited for
NVIS type operation, there should not be too much high angle
radiation, unless the pattern is distorted by the car body. I've
always noticed on 80m, late night is always better than early evening
when the skip is short. But even if you wanted to test, you could have
a guy off about 200 miles to do a "double check" of the high angle
operation. The hard part is the varying propagation. I think that in
itself, is the main reason for the ground wave tests. Here at home, I
can tell which of mine are best just by the receiver readings alone.
If you really wanted to even things up, place all antennas on the same
flat ground system to test. But then, that takes away the fun of
trying to improve the car ground, height, etc.. MK

If you read my description below you will see I used 450-Ohm ladder
line 65 feet in length.

The calculations for the input impedance was done using TL Details
software by Dan Maquire AC6LC. A very nice freeware program.

I don't know anybody who disagrees with that. What I disagree with is
the adoption of the steady-state model as a religion which, in turn,
dictates reality, e.g. standing waves that exist without reflected
waves.

Modulation and noise can easily prove that wave energy is making a
round trip from a mismatched load back to the match point and back
to the load, ad infinitum. The steady-state model does not cause
those reflections to disappear from reality.

All stainless steel hose clamp. Clen the surfaces, use some Noalox and clamp
the wire to the tubing with hose clamp. Good contact and removable.

Add "in one direction" and you will have it. No such constraints about the other directions. The 'lost' enery can simply flow in another direction.

> A cancelled radio wave is neither conveyed nor redirected. It must then,
> be absorbed.

Nope, the energy in a canceled EM wave will simply go the other direction, just like canceled light reflections in a non-glare thin-film coating. The Melles-Griot web page says that the energy in canceled EM waves is NOT absorbed or lost. It says the energy 'lost' in the reflected wave cancellation process joins the forward wave as "enhanced intensity". Here's the quote:

"If the two reflections are of equal amplitude, then this amplitude (and hence intensity) minimum will be zero."

Rearward-traveling reflected waves are canceled at the air to thin-film boundary.

"In the absence of absorption or scatter, the principle of conservation of energy indicates all "lost" reflected intensity will appear as enhanced intensity in the transmitted beam."

Energy from the canceled reflected waves joins the forward wave.

The same thing happens at the match point in a transmission line and works even better than non-glare thin-films for light since we are dealing with single frequency coherent collimated waves within a transmission line.

And I'm not addressing those people. The ones I disagree with are the ones who say reflected waves cease to exist the instant that steady-state is achieved. I know you don't believe that, Richard.

Or better yet, just feed the transmission line at a current maximum
point as described on my web page. All transmitter end impedances
are resistive and between 35 ohms and 85 ohms - no tuner needed.

Attach an aluminum clamp to the tubing and then attach the lug to
the aluminum clamp. Be sure the lug is tinned with solder which is
a fair dissimilar metals contact for aluminum.

who ever said they 'cease to exist'???? the great power of the steady state model is that the reflections have reflected enough times that each additional reflection is of negligible magnitude, at this point the currents, voltages, and yes, even the powers traveling in each direction along the line are at essentially constant values (the 'steady state') and you no longer have to look at each reflection separately. that is the great shortcoming of the arguments you have been presenting, you are taking a snapshot of what is really an infinite summation of reflections in both directions along a line between the mismatch points, and that is why it is so hard to use the exact solution, you have to sum each reflection until you get tired of doing it or reach the same value that the steady state solution gives you in one step. so its not that the steady state solution ignores the reflections, it has all the reflections already summed up in one neat package.

you know what is also funny... if you go into detail and analyze what Hecht is doing in Optics, most of those simple statements and thumbrules about reflected intensities, glare cancellation, and interference are a result of the steady state solution.... it happens so quickly at those frequencies that they don't even bother discussing the intermediate steps, they go right to the final solution... which is of course the 'steady state' for the system. if you went into complete analysis of a thin film that cancels reflections you would have to sum a multitude of internal reflections until you found that after many internal reflections they eventually canceled the initial reflection and voila.... steady state with no reflection, just like a coaxial matching section... complete with its forward and backward wave components and reflections at each impedance discontinuity.

498. Re: Attic HF Antenna - Any Good Designs?

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-06 21:00:56 UTC
From: Ron <rmrippy@hotmail.com>
Message-ID: <3F088CC1.2060605@hotmail.com>
Source record: 113342

I have a buddipole in my attic mounted on a camera tripod. This makes a simple and neat installation, but is not working out as well as I would like (no reflection on the buddipole, which is fine product). I am using an Icom 746pro, getting some RFI on the TV, telephone, etc and am wondering if an inverted V running under the eave of the house and fed at the peak of the roof would work any better. I live in an end unit condo and the eave faces an open field. Any opinions on this?

Source record: 113344

I have reservations regarding the validity of mobile antenna shootouts.

First, I have never participated in one or even witnessed one. With that disclaimer on the record I'll proceed.

I managed an antenna range for five years. On the range we measured antenna performance for satellites and military missiles on US government contract.

We would not consider any measurement within 1000 wavelengths as indicating valid field intensity [looking for a uniform plane of the Poynting Vector]. We also measured AZ-EL characteristics.

Translating that to 80 meters requires that the receiving antenna be located 80 kilometers [~ 50 miles] from the source and also that the source be rotatable in AZ-EL.

Seems to raise questions regarding how valid is the measurement of a ham mobile antenna on a vehicle made at ground level at a range of 100 meters or 1 mile.

The data from shootouts is the data. But, interpreting that one slice out of a two dimensional hemisphere to claim one is better than the other takes a big leap of faith.

502. antenna design for 418Khz

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-06 21:35:17 UTC
From: Peter K <posttonews@btinternet.com>
Message-ID: <bea4ml$n9h$1@sparta.btinternet.com>
Source record: 113346

Can anyone point me at a site with "homebrewed" solutions for a receiving antenna for RTTY (navtex) on 418KHz?
The antenna is for use on a small yacht and therefore I've dismissed loop designs on directional grounds. I've got acceptable results using 2.4m of 1 1/4" waste pipe wound with around 320m of 30swg enameled wire but I would like to reduce the length.
Am I "playing" in the right area?
I was thinking of breaking the winding in the middle and connecting coax to make a dipole feeding into the 50ohm receiver socket.
Another idea was the mast and rigging wires all run from a fibreglass (insulated? for radio frequencies?) hull could they be used ?

Thanks

Peter K

So even you agree that there is wave cancellation. Now all you have to
convince us of is those canceled waves carried zero energy. Good luck.

504. Using a G5RV on 60m

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-06 21:36:50 UTC
From: restamp@hotmail.com
Message-ID: <SD0Oa.148437$BA.50588475@twister.columbus.rr.com>
Source record: 113347

I got on the new 60m band today using my G5RV and had a few
very nice QSOs.

The G5RV is essentially a 102 ft dipole. Empirically, it tunes
up fine on 60m (with a transmatch). My question is: How much
gain does it exhibit over a 88 ft true-blue 60m dipole? My guess:
Not much, as it is only 16% long. However, the FCC does mandate
that we "do the calculations" for non-dipole antennas to ensure
we do not exceed the 50W ERP requirement.

So, can anyone tell me what the gain of a G5RV exhibits on the
60m band so I can determine what power limits I need to observe
for that band?

Thanks in advance,
Rob Stampfli

If you look at it like this, an 80m mobile antenna is very short in terms of wavelength. As such, the biggest problem is efficiency, getting as much rf out as possible without ground and I**R losses dropping efficiency below a few percent. In a shootout what I would try to do is squeeze another few % efficiency, and not worry about elevation angles and that sort of thing, as I would do on my own 80m mobile. I think this is the deal with shootouts, the best efficiency of a short 80m antenna as measured by an FSM a couple hundred meters away.
If you have an antenna with high efficiency, then you change the playing field.

> size) does not have significant impact on efficiency of mobile antenna. That's
> measured and "reasoned" by W8JI.

I disagree though, but not because of wire size. Some coils are extra
lossy. Usually from using thin wire, with a very tight winding ratio.
But there is a design problem with the hustler coils and their metal
end caps, if I remember right.
I forgot exactly what the deal was, but it should be in google. I
agree in *most* cases, ground losses will overshadow coil losses, but
if the coil is bad enough, it's loss then becomes noticable. If this
were not the case, I could use the hustler coil with the same results
as my homemade "bugcatcher" style coils. But I can't.
In some respects the extra loss in the hustler coil is intentional
from what I hear. They wanted to make it easier to get a usable match
on most any car. But I don't like using excess coil loss as a psuedo
"matching device". In my coil testing here, I've found thin wire coils
can be quite efficient if the winding ratio is optimum. One of my "pet
peeve" screwdriver brands also uses excess coil loss as an aid to
matching, or to avoid the use of a matching device altogether. The
coils are about 1.5 to 2 inches dia, and use thin wire wound very
tightly. A friend of mine had one and was trying to set the matching
device. I doodled with it a while, and it was horrible. So much coil
loss, you had trouble hearing a noise peak as you tuned the coil.
Really bad...Maybe the worst mobile antenna I've ever seen. And it's
called a "screwdriver". Just to show, all screwdrivers are not alike.
Not by a long shot. MK

Dave, you have to remember that "shootout" measurements are relative, not absolute. I've never heard any of the "shootout" proponents claim that they're accurately measuring field intensity -- just relative field intensity, a much, much easier problem -- particularly when all the radiators are essentially vertically polarized and electrically short. So all have very nearly the same polarization and vertical pattern.

About the weakest point I see in the measurements (assuming properly calibrated field strength meters, and care taken in keeping power input and physical position constant) is the uneven horizontal patterns caused by the vehicles. And while I'd be skeptical of fractional dB accuracy, I'd regard differences of a few dB to be pretty indicative of relative antenna performance in the field.

I would treat it like a dipole and not worry about it. Whaterver small gain
it has is probably used up in losses in the feedline and matching. YOu are
probably loosing more than enough in the transmatch to make up the
differance in the gain.

Installing a ground rod at the bottom of the tower hole and using heavy braid to connect it to the tower is a way of grounding the tower also and has the benefit of "no bends" in the conductor going to the ground rod. With a ground rod next to the tower/concrete base, essentially half of the area available to the ground rod for dissipating the energy is absent (i.e. the volume presented by the concrete). Of course, after the tower is installed eliminates this option.

And Roy,
The signal strength range from a simple whip and tuner to (for example) a
102" whip on a bugcatcher on a hustler base (ie. BIG, RESONANT AND MATCHED)
is more like several s-units than a few db.
After decades of tuning HF mobile antennas with field strength meters
located on the hood or miles away I have concluded that if the field
strength
up close gets better, it usually gets better far away, as well.
And that condition coincides with a resonant, matched antenna.
Nothing wrong with shootouts;
Just remember it's a limited data set and avoid any "real" shootouts!

I've built several 'delta' and 'Cody War Kites' to lift 500-650 feet of
antenna wire. A good source for info and kites: http://www.intothewind.com/
good luck,

Ken

> convince us of is those canceled waves carried zero energy. Good luck.

sure, when you superimpose fields they can cancel each other. that is seen
by solving for the voltage and/or current at an impedance discontinuity.

try this exercise:

100v AC 50 ohm source ------50 ohm 1 wave------|----75 ohm 1/2 wave----| 50
ohm resistive load

for the purposes of this exercise the cables are lossless, and the source
can be modeled as a perfect sinusoidal voltage source in series with a 50
ohm resistance. the 50 ohm line is 1 wavelength at the frequency of the
source. the 75 ohm line is 1/2 electrical wavelength at the frequency of the
source. the source is turned on at time=0 and is a sine wave starting at 0
degrees phase. The period of the source is 1 usec.

show wave components on both sides of the 50-75 ohm cable junction from:
t=0 to 1 usec
t=1 to 2 usec
t=2 to 3 usec
t=3 to 4 usec
t=4 to 5 usec
and
t=100 to 101 usec

I'm almost certain the last time I went to HRO Phoenix (last month)
the BB3 display was still mounted on a table back by the other
antennas. Maybe it's just a local thing as HRO Phoenix is the closest
HRO to the Nott BB3 factory in Farmington New Mexico. I have been
there twice. Nice people to deal with. You have piqued my interest
though, and I will check with HRO when we go to Phoenix next week.

>from what I hear.

That's what I thought, besides, big coils look impressive, but...

Here is the part of Barry's W9UCW posting on TopBand reflector explaining his work and findings: (again that is measured and not 'splained by W8JI "theories")

>>As for the HI-Q vs. LO-Q loading coil discussion, I would like to offer up a sampling of results from a massive study of inductively loaded verticals, especially mobile antennas. Most of this data was collected over a period of 3 years at a test site built near Fletcher, NC. A goodly number of people were involved. Thousands of measurements were made and all test series were repeated many times. There were near-field and far-field pick-up points and a dozen or so parameters were measured.

This all started with the "Q" question. It was the big issue when I started mobiling on 75 and 160 around 1960. Many of us enjoyed the increased band width and low amount of proximity effects of long, skinny resonators, and seemingly felt no difference in signal compared to the big open HI-Q coils, where a little rain or a small bug put you out of band. Unscientific you say? You bet.

Around 1970, some guys from Argonne Labs, in an effort to show us the error of our ways, brought down equipment to a "160 Meter Reunion" and set up a measurement program. About 75 people were there. On the "Q" question, the comparison was between similarly laid out center/top loaded antennas. One had a big open wound, heavy wire, spaced turn coil with a 8" diameter and a

1:1 length/diameter ratio. The other had a 1" diameter close wound coil on a PVC form using #20 wire. The length/diameter ratio was over 20:1. It was covered with shrink tubing.

The measured worst case scenario (of any HF band) was on 160. The difference was .3db. That's 3 tenths. We were all shocked and immediately agreed that the test had to be flawed...even those of us that thought the LO-Q coil was a better deal. It just couldn't be that close.

That test was modified and tried over and over. I know of 5 more run between 1972 and 1992....all with the same results. Personally, the big beasty open HI-Q coils look like "real radio" to me. There's just no real reason to use them unless you prefer pinpoint bandwidth and terrible "proximity" problems. We reconfirmed the numbers in the Fletcher Program.

The reason the difference is small is that the current diminishes so rapidly in the first few turns of lumped inductance, whether Hi-Q or LO-Q, and therefore only the loss in those turns is being compared. The same is true for inductively top loaded base station verticals. Loss in the coil is insignificant. Most calculations to the contrary made in texts, articles and some modeling programs are based on the current being equal throughout the coil. This is not true. Of course, most mentions of this loss are not quantified at all.

On the other hand, the position of the coil in the available vertical mast means everything. Here's the bottom line: All other factors being the same, the inductively loaded vertical with the longest mast between feed point and lumped inductance wins the radiated field strength contest. This means that a standard Hustler setup is louder than any "Screwdriver" or "Bug Catcher" unless they have more than
4½' of mast below the coil. We confirmed that in Fletcher, too. As an example, for 80M, a 9ft. top loaded mast was down 20.5db from a full quarter wave, both measured on the test stand. The base loaded 9 ft. mast was 36.5db down, a difference of 16db. BTW, the same mast loaded with a Smart tuner or Icom AH-4 was 44.5db down. Results are worse on 160.

Bandwidth is controlled by two things; the length/diameter ratio of the inductor and the capacitance/inductance ratio of the resonator. (Top whip or hat to coil inductance)….higher means wider in both cases
<< (de W9UCW)

Seems that Hustler tried to "match" the low band resonators by introducing some extra loses in their loading coils. I rewound the resonators with 1/4" copper tubing (20 and up) but in view of W9UCW findings maybe there is good compromise between ugliness and performance.

>Where does one buy aluminum solder?

See http://www.rcfaq.com/answers/engines/solderalum.htm for some
suggestions. It's definitely available.

I've even heard people report that they've been able to solder
reliably to aluminum using a combination of ordinary 64/40 solder,
activated rosin flux, and a bit of trickery involving a dentist's
pick. The trick is this: flux the joint well, heat thoroughly, apply
some solder (it'll bead up and won't stick). Then, take the dentist's
pick, and while continuing to heat the solder and junction, scrape the
pick _through_ the bead of molten solder and scratch the surface of
the aluminum underneath (naturally, the pick has to be hot enough that
it doesn't cause the solder to congeal).

The scratching action breaks up the layer of oxide on the surface of
the aluminum. If the molten solder is lying right on the metal, it
(and the remnants of the flux) will exclude oxygen long enough to
allow the solder to fuse with the aluminum.

As a matter of fact, a 138" whip with SGC-230 was 12 dB down from the top
rated bugcatcher and screwdriver.

I recall reading a treatise many years ago where the author made the case that any attempt to solder copper to aluminum was doomed to failure. His argument was that there would inevitably be corrosion at the interface due to the large electrochemical difference between the two metals and, although the joint might be initially sound, it was bound to fail after some length of time.

I've never tried soldering aluminum so don't have any direct experience. Has anyone had an aluminum-copper joint that's remained strong after several years? If so, indoors or outdoors?

Hmmm... good point.

The URL I quoted did make the point that soldered aluminum joints are
not particularly strong. The usual capillary action during soldering
doesn't take place, so you have to fillet the joint to build up enough
metal to provide strength.

Welding is apparently preferable if mechanical strength is required.

>I've never tried soldering aluminum so don't have any direct experience.
>Has anyone had an aluminum-copper joint that's remained strong after
>several years? If so, indoors or outdoors?

No data, sorry.

Another possibility might be to use one of the professional "COPALUM"
copper-to-aluminum crimping systems, designed for doing safety
upgrades in small-gauge aluminum wiring systems in houses. These
crimp sleeves need a lot of pressure to apply properly, though, and
the equipment isn't all that easy to come by.

David Robbins wrote:
> try this exercise:
>
> 100v AC 50 ohm source ------50 ohm 1 wave------|----75 ohm 1/2 wave----| 50
> ohm resistive load

The forward power on the 50 ohm line is 200W. The reflected power on the 200 ohm line is 0W. The forward power on the 75 ohm line is 208.33W. The reflected power on the 75 ohm line is 8.33W. The physical reflection coefficient rho = (75-50)/(75+50) = 0.2 making rho^2 = 0.04.

200W(rho^2) = 8W reflected, 200W(1-rho^2) = 192W transmitted

8.33W(rho^2) = 0.33W re-reflected, 8.33W(1-rho^2) = 8W not re-reflected

The reflected component voltages on the source side are 20V at zero deg and 20V at 180 deg which causes cancellation of the reflected wave toward the source. There's 16W of destructive interference.

The forward component voltages on the load side are 120V at zero deg and 5V at zero deg which causes a forward voltage on the 75 ohm line of 125V. There's 16W of constructive interference. The reflected voltage is 25V on the 75 ohm line and arrives out of phase with the 125V of forward voltage so the voltage at the impedance discontinuity is 100v.

535. Coax to scanner extention?

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-07 04:01:44 UTC
From: achilles03@hotmail.com
Message-ID: <fef44ceb.0307062001.240da0cd@posting.google.com>
Source record: 113279

I'm still getting my feet wet in the world of AR, and was hoping to learn some from the more experienced people in this group.

I was planning on using my scanner while listening to an airborne transmitter. However, I know the car frame causes a lot of path loss (anyone happen to know a ballpark figure right off the top of their head?). Therefore, I was planning on placing the antenna outside the car and running a coax inside the car. My questions are:

1. Does it matter what area of the car I place the antenna on? Or is the only thing that matters the fact that the antenna is outside of the car's faraday cage?

2. How much loss in scanner sensitivity can I expect with, say, a 6ft coax inserted? (I imagine not much, but I'm just curious).

Thanks in advance for anyone who has any insight or information!
Dave

Actually, I've made the connection as one poster suggested -- clamped the wire under a stainless steel clamp. It does seem to be slowly corroding the aluminum, but after 20 years outside in the rain, the corrosion still isn't bad. Some Noalox would probably would have helped.

Aluminum actually takes solder pretty well. 60/40 solid core solder and a
little 20 weight motor oil for flux. The trick is to get rid of any existing
oxidation and prevent it from oxidizing using the oil. I just won some beer
moneey by soldering a tab top to a piece of wire. Didnt want a soldered
joint though.

Lightning does some pretty weird stuff.
Several years ago I was given a Radio Shack Color cumpter that had been
struck by lightning. Upon checking it out I found all the ICs and power
supply was good. After pullling the microprocessor from its socket I noticed
3 runs on the pc board that was vaporized. I repaired the runs and the
computer worked as good as new. Runs were on the sddress lines. Go Figure.

Reflection of waves off the car surface can affect the sensitivity in various directions, and height above ground will increase range. So the best position is in the center of the top of the car. But any position outside the car will be considerably better than being inside the car. Although the car body shields incoming waves, it doesn't make much of a Faraday cage at aviation-band frequencies because the window and winshield holes are quite large in terms of wavelength. (If they weren't, and the car body really did make an effective Faraday cage, you wouldn't be able to hear hardly anything at all from inside the car.)

The loss of 6 feet of RG-58 size coax, or even very small RG-174 size coax, will be negligible (less than 1 dB) at aviation band frequencies.

Aluminium solder is available from e.g. Maplins and Farnell / RS in the UK.

I also have heard that removing the oxide layer by scratching the surface whilst under an oil film then soldering with ordinary solder works OK.

Using Aluminium solder makes soldering aluminium seem pretty much the same as soldering copper / tinned copper things together - Aluminium needs to be really clean though and just scratched clean - I think the oxide layer forms instantly
(microseconds?) but the aluminium solder flux seems to take care of it.
I also use it to patch up holes in the aluminium grill pan which seem to appear
remarkably frequently...

Aluminum-soldered connections to both brass and aluminum have lasted more than ten years outdoors on the moonbounce array, here in the moderately damp English climate... and they'll probably be good for another ten.

Aluminum soldering is possible, but not easy. Here are a few tips that I found out the hard way.

The connections were all drilled through the larger piece and pinned with a screw for mechanical strength, so the joint cannot possible flex or move. Then add the solder for electrical continuity *only*. This is important for antenna work - never rely on solder alone for mechanical strength. It doesn't ever have much strength, and if you allow solder to be flexed by the wind, it will very quickly fatigue, crystallize and break.

Aluminum soldering is tricky. Practise on some scrap pieces, because you *will* make a mess of it first time!

To make the solder work, it is *essential* to file and scrape the aluminum absolutely clean and bright, and to degrease it with solvent. (A thin, invisible film of aluminum oxide re-forms instantly. The special flux will take care of that, but don't expect it to handle any corrosion that's heavy enough to be visible.) Whenever I tried a short-cut, the solder failed to run properly and the whole thing turned into a cruddy mess. The cleanup/rescue job then took much, much longer and the finished result was never as good as when I'd taken the trouble to get it right first time.

Because aluminum is very good at conducting heat away from the joint, and the metal pieces will probably be large, you'll need a torch (butane is OK, but a butane/propane mix gives a bit more heating power). Use the hot gases *outside* of the visible flame to heat the metal, not the flame itself. Move the flame all around the metal - front, sides, top,

bottom and around the back - so it all comes up to the same temperature at the same time. From time to time, remove the flame and just touch the hot metal with the end of the solder, until the solder melted and runs freely around the joint.

Don't let the aluminum get too hot! The melting temperature of aluminum solder is quite high, and there is a narrow range between the metal being hot enough to melt the solder, and becoming so hot that it oxidizes. If you see a cruddy oxide layer form, you've already passed the point of no return and the joint is a failure. The *only* way forward is then to let it cool, file away all the crud and start again. Do *not* try to rescue an oxidized joint by adding more heat and more solder - it won't work, and it only makes the cleanup job harder.

When the pieces are just hot enough, the solder runs freely just like normal tin-lead, and makes a neat fillet. (If the joint looks at all lumpy and rough, it's a failure.) When the aluminum surface is properly 'tinned' with the special solder, it's possible to continue with regular cored tin-lead solder, which is easier to work.

On my antennas, the finished joints were lightly sprayed with polyurethane to keep moisture away, but this flaked off after a few years. After ten years there was only light corrosion, confined to the solder itself, and it wasn't at all serious.

So much for the good news. The bad news is that the I tried several aluminum solders, and only one of them worked (for me). Unfortunately that solder only came in little packets that had been re-branded by the supplier, who have since discontinued it. I never did find out what the original make was.

It is my meaning that you do not need any amplifier, on the SW bands it is
not veak signal strenght that is a problem it is the strong signals that is
the problem. I can only recomend you to build a passive preselector, that
is what you realy need, I have build one and it is working very, very well.
You can find the buildinginstructions here

http://www.bavarian-contest-club.de/projects/presel/list.htm

If you have any problems with building one, please mail me.

Regards Max

SWL and HAM.

The oxidation can probably be prevented by doing the soldering in a nitrogen
filled box.

I have always believed in the steady-state solution, David, because it gives correct answers. What I don't believe in is the steady-state religion with its reflected waves that don't exist. In fact, the s-parameter steady-state solution assumes that forward and reflected waves exist and that two reflected wave components cancel to cause 'b1' to equal zero.

What you seem to have missed is that I performed the steady-state solution using *average powers* to obtain the RMS voltages. Like the HP Application Note, AN 95-1, says, "Power gain and mismatch loss are often of more interest than the corresponding voltage functions."

The entire discussion has boiled down to one point. When wave components cancel in a transmission line and thus cease to exist, what happens to the energy that pre-existed in those canceled wave components?

Around here in Texas, atmospheric noise is also a huge problem which
an amplifier won't help.

Cecil, W5DXP wrote:
"Nope, the energy in a canceled EM wave will simply go the other direction, just like canceled light in a non-glare thin-film coating."

Energy which simply goes the other direction is not canceled. It is redirected. Cancel is the wrong word. Reflect is the right word.

In Cecil`s example of a 1/2-wave of higher impedance transmission line inserted in a 50-ohm system, there are internal reflections at each end of the foreign line, but none in the 50-ohm part of the system.

The load resistance is too low for the foreign line.

Reflected voltage has reversed phase..

Total phase shift for voltage in a round-trip through 1/2-wave of foreign transmission line is 360-degrees plus 180-degrees in reflection from the low impedance.

Reflected voltage is out-of-phase with incident voltage at the load and at input to the foreign line.

Reflected current is not reversed in polarity at the load or back at the source of new current.

Reflected voltage and current combine at the input of the foreign line to drop impedance presented to the generator to 50-ohms.

As in the case of incident energy being reflected at the load end of the foreign line, reflected energy is re-reflected at the source end.

The re-reflection puts voltage back in-phase with the new voltage.

Reflected current was not phase inverted by first reflection, nor is it inverted by re-reflection. The impedance is too low on both ends for the foreign transmission line.

New volts and amps entering the transmission system are nearly indistinguishable from the re-reflected energy, so there is a merger.

Best regards, Richard Harrison, KB5WZI

Hank,

Another antenna wouldn't do you any good. You need a rotator, as the channels are not all in the same direction. If you were to get a non directional antenna, then all channels would come in equally poor. If you put up two antennas, you can't combine them with a splitte; you would have to install an A/B switch.

>
> The entire discussion has boiled down to one point. When wave components
> cancel in a transmission line and thus cease to exist, what happens to the
> energy that pre-existed in those canceled wave components?

and your answer showed just where that happens... by stating that the
voltage at the 50/75 ohm discontinuity is 100v all the wave components are
accounted for right there. the 'cancellation' occurs AT the discontinuity
where you do the summation of currents and voltages, therefore there can be
no waves to cancel further down the transmission line in either direction.

think about destructive interference this way, if you are 1 wavelength down
the line from the discontinuity and are looking for the waves that
destructively interfere with each other what do you see? nothing, the waves
have already canceled each other... so, move closer to the discontinuity,
say at 1/2 wavelength... still nothing, the waves have already canceled...
move closer, still nothing... closer, still nothing, get right up to the
discontinuity, but not touching it... still nothing... there couldn't be
anything at any distance away from the discontinuity or there would not be
complete cancellation at any distance. so what is left? the cancellation
occurs exactly at the discontinuity and the waves never propagate down the
line at all, it is an absolutely necessary part of the wave solution in the
line. if you could ever actually find a point away from the discontinuity
where those waves existed before they canceled each other, they would never

be able to cancel as they would not be in the right phase and magnitude relation to each other to start with, and they can't change relative phases or amplitudes as they propagate.

the same goes on the other side for the constructive interference. you can never find a point away from the discontinuity where you could see the separate waves that haven't combined... so all the interference occurs at a single point and you can draw any size bubble around it you want and sum up powers, voltages, currents, etc and they will all add up... but you really only need to look at that one point.

561. Re: tower grounding

common practice with us is to put in 4 8ft ground rods then connect them all together and then to the tower. A static disipator (baby bottle brush looking gizmo) at the top and its own run of wire to grnd. is a great help.

Jimmy wrote:
"Runs were on the address lines."

This is reasonable as address lines can operate with external devices.

An example is a data modem connected with a phone line. Phone lines are usually arrested to the same ground used by the commercial power. This is to minimize surge voltage difference between power and phone lines.

If one of these lines takes a hit and the other doesn`t take the same hit by the time it arrives at your machine, your computer may be the most susceptible breakdown site should protection fail.

Any external device, not just a modem, poses a hazard which depends on its exposure to lightning.

Best regards, Richard Harrison, KB5WZI

Lighten up, Airy. Dave's software collection would be outstanding if he charged for it. Having it available for free is an incredible bargain.

If you don't care for automated things, fine, but at least get your facts straight. None of Dave's software works a station for you. None of it builds, assembles or tests your hardware. If you want to live in the '50's, ok, but please don't criticize those of us who like a little progress from time to time.

Best way is to have a stainless clamp with a tab that first touches
the aluminum. The copper wire then goes between the tab and the clamps
band. That way the copper wire never touches the aluminum. Copper will
cause the aluminum to corrode quickly.

With a standard clamp you are left pretty much with contact of the
wire only to the stainless clamp. The other part of the clamp
providing contact to the aluminum.

The same type of clamp with a tab is recommended when connecting
copper wire to a galvanized tower. The copper will quickly destroy the
galvanized coating if in direct contact with it.

Back in the "OLD CORPS" where I learned to solder
strength was always built mechanically, not wit
solder. When making a connection if you could not
identify every lead in a connection you had used
far too much solder. Does not matter whether it
is copper on copper, aluminum on aluminum, or
whatever on whatever, solder is for electrical
connection only not mechanical strength.

566. Re: tower grounding

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-07 15:42:46 UTC
From: Gary Schafer <gaschafer@comcast.net>
Message-ID: <u15jgvg0j50115snka4j1o34se6elohm0b@4ax.com>
Source record: 113308

4 ground rods is a great help but it would be much better to place
them around the tower and run a separate lead from each to the tower.
Much lower inductance that way. If they are placed around the tower,
tying the rods together is a waste of wire. The extra wire could be
put to better use as a radial.

A ground lead running down the tower is also a waste of wire unless
the tower is made of wood. A metal tower will have many times less
inductance than the wire you run down it. Again the extra wire would
be much better if used as a buried radial.

Bonding the tower leg joints with a strap around each is a help.

The only help the static dissipater brushes give is decoration on the
tower. If for some reason someone prefers that look then ok.
For any kind of lightning protection a rabbits foot hung on the tower
works as well.

Yes you can combine the antennas with a splitter.
That is why they are called splitter/combiners.
The bad news is that you get almost one half the
energy out of a splitter/combiner that you put in.
There is a nearly 3db (50%) insertion loss. If
you had two antennas, each pointed in a different
direction you might solve your problem. The rotor
is probably the most aestically pleasing solution,
and not that much more expensive than the best
antenna mounted amplifier that R/S sells, $60 for
the amplifier vs. $70 for the rotor. With an
antenna the amp should be mounted at the antenna,
it is broadbanded (if you plan to operate your
station at all, no one it the house will watch TV
while you are on the air.

Lighten up, Bill. Ham Radio is all about personal
technical achievement, and not about some automated
process doing the work for you. If the DX is going to be identified and
tracked for you, with your rig being tuned for you, as was implied,
then you might as well claim DXCC from using a GSM mobile
phone, because your "achievement" will be indistinguishable.

As to price, a CB rig being given away for free is still a CB rig.

Now that the Morse requirement is being done away with,
perhaps it is time to ask again what is the difference between a CB
operator and a Radio Ham?

A highpass filter could serve as a lightning arrestor.
In the one shown below, for VHF, C1 could be a 27pF
'doorknob' capacitor rated at 5kV and L1, L2 could each
be 5 turns of #12 wire, 1 inch in diameter. I think you
get the idea.

Reg's program Dipole 3 has default calculations for a "standard" G5RV and
lets you adjust each item your self.
My 90 foot dipole with Paralell line does fine.
A standard G5RV with the Standard Coax length loses 56% of its power in the
coax.

I didn't say the *energy* was canceled, Righard. I said the *wave* was canceled. Energy cannot be canceled but waves can be canceled. Canceled waves don't reflect, they are destroyed. Energy left over from wave cancellation event can be thought of as being reflected since it changes directions.

> As in the case of incident energy being reflected at the load end of the
> foreign line, reflected energy is re-reflected at the source end.

What is the mechanism of physics that causes 100% re-reflection? There is no short, open, or pure reactance at the match point.

Lighten up, Francis...

When you key a mic, or tap a key, there is an "automated process"
taking place.

That's right. "PERSONAL technical achievement". Perhaps there are
HAMS who enjoy modern technology interlacing with traditional items
like HF. Perhaps this particular HAM enjoys the orchestration of various
software processes that he manages and configures to enhance his very
PERSONAL technical achievement within the hobby?

Perhaps it is time to ask again, what have all these whiny, crybaby types
done to advance the service, or at least keep it in line with the real
world?

As far as CB-esque operators, HF is chock FULL of them, Morse code
requirment or NOT. I avoid HF like I avoid CB, and for the EXACT same
reasons!

Personally, I think an activity like HAM radio should be one where each
licensee must make certain achievements, or they forfeit the license. Such
as advance from 5wpm to something higher, or integrating modern technology
into the communication mix. If CW is a mandatory requirement (and I think it
should be), then so should areas like the digital modes, and the microwave
end.

Do you know your DHCP from your RHCP or LHCP? Doubt it!

Sitting back saying CW is the end-all, and bitching like 5 year olds does
absolutely
nothing for the hobby. At least nothing good.

As you were. 73.

> accounted for right there.

Yes, that is exactly what I have been saying. My web page article specifically states that *ALL* of the destructive interference and constructive interference happens at the match *point* and nowhere else. Here is a quote from that article which I wrote about a year ago:

"The impedance discontinuity point, like other geometric points, is infinitesimal and has no dimensions. In other words, the source side of the impedance discontinuity point and the load side of the impedance discontinuity point are the same point and are not physically separate from each other. Since a diagram cannot occupy a point, any diagram is, of necessity, in two dimensions but that does not mean or imply that anything happens at any real-world distance from either side of the point. EVERYTHING DISCUSSED HERE HAPPENS AT EXACTLY THE IMPEDANCE DISCONTINUITY POINT, NOT ANYWHERE ELSE." Capitals here, bold italics in the article.

> the 'cancellation' occurs AT the discontinuity
> where you do the summation of currents and voltages, therefore there can be
> no waves to cancel further down the transmission line in either direction.

Yes, exactly what my web article says. See above.

> think about destructive interference this way, if you are 1 wavelength down
> the line from the discontinuity and are looking for the waves that
> destructively interfere with each other what do you see? nothing, the waves

Jim, K7JEB wrote:
"A highpass filter could serve as a lightning arrester."

Lightning contains a spectrum of frequencies. Any bandpass restriction reduces exposure to damage. Most applications don`t require allpass connections. Might as well limit passband.

Tower lighting chokes are made which carry a lot of amps. These are used on AM broadcast tower lighting circuits to avoid shorting the r-f on the tower to ground through the tower lighting circuits. They also very successfully keep lightning out of the plant`s a-c circuits. These chokes with bypass capacitors on the plant side form a lowpass filter.

I`ve used the same tower lighting chokes very successfully to protect a wide variety of electrical equipment from surges on the power line. My first protection job was the first Motorrola transistor base station to be marketed. Motorola tried many schemes to prevent lightning destruction to no avail. My tower lighting chokes with appropriate arresters and capacitors solved the problem. It was immediately widely imitated and used for many other devices, not just transistor radios.

Best regards, Richard Harrison, KB5WZI

The power in a traveling wave is |V*I|. That's the number of joules
of energy that passes a point in a second. Waves CANNOT exist without
energy. If waves contain energy, then they give up that energy when
they are destroyed by wave cancellation. The waves cease to exist
at the point of cancellation. The energy in those waves CANNOT cease
to exist. You agree that wave cancellation exists. Walter Maxwell
agrees that wave cancellation exists. Steven Best agrees that wave
cancellation exists. The question is: What happens to the pre-existing
energy in waves that are going to be canceled. You somehow make it
disappear, at least in your wet dreams, by saying canceled waves didn't
contain any energy before they were canceled. (Those grapes were probably
sour! :-) Steven Best just lets the energy fade away toward the source
but never reach the source. Walter Maxwell has his "virtual short".
Energy direction-of-flow reversal during the wave cancellation event makes
the most sense to me from a Conservation of Energy point of view, and I am
working on a physics explanation hopefully acceptable to you and others.

but you see, you have been talking about waves getting canceled... a wave can not exist at a POINT. so all the diagrams you were drawing about waves going this way and that from the mismatch point were misleading those who hadn't read your web page, which is probably most of those on this group. your further arguments about optics and trying to overlay phase shifted lasers were just adding to that impression that you really were trying to cancel waves somewhere down the line which is obviously impossible.

OK, to be entirely technically correct, wave*fronts*, existing at a point,
are what get canceled. Jeeezzzzz, that's just a silly semantics difference.

> your further arguments about optics and trying to overlay phase shifted

Are they?

Granted DHCP is a protocol for TCP/IP networks; however,
TCP/IP networking and HAM radio have overlaps and literal
interconnections.

Radio astronomy? Hmmm...RHCP and LHCP have more to
do with wave polarity than astronomy.

Looks like you might have done a rudimentary search on the
Internet for these technologies.

In any case, the point being that NO aspect of the ARS is more
important than the next. Since life and knowledge are dynamic,
so will be activities such as the ARS.

As Morse code is a required proficiency, so should all other
aspects, even TCP/IP, encryption, and yes, software automation.

Licenses should be renewed and re-tested for every 5 years or
less.

All in the name of personal technical achievement. :-)

But power doesn't propagate.

> If waves contain energy, then they give up that energy when
> they are destroyed by wave cancellation.

Define "contain energy".

Energy is certainly required in order create a wave. But energy is not consumed by wave propagation. If energy is not utilized at the terminus, no energy is transferred by the wave to the terminus. Energy may or may not be transferred by other waves associated with the source which stimulated the waves in question.

> The energy in those waves CANNOT cease
> to exist.

Define "energy in waves". Waves launched from a boundary are representative of an amount of energy available at that boundary, but they are not necessarily indicative of a transfer of energy in the direction of those waves - as we can see in the case of wave cancellation.

> The question is: What happens to the pre-existing
> energy in waves that are going to be canceled.

First of all, I have no idea what "pre-existing energy" is supposed to mean. Secondly, I don't know how to parse "waves that are going to be cancelled". Are you asking about what happens in the transient period?

Energy is obviously NOT conserved within that boundary. The energy inside the boundary decreses as energy passes out of the bounded volume. It's a perfect example of what I was saying. It's exactly the same as the power plant example I gave. Jeez.

Hi all,

I've been trying to find some data on what happens to the feedpoint impedence of an antenna when the thickness of the wire increases. I know for a fact the bandwidth will increase somewhat but what does the impedence do, say going from 14 gauge to 10 gauge copper wire? Does it increase or decrease?

Jeff Y.

> Bonding the tower leg joints with a strap around each is a help.
>

The tower legs are connected at the bottom with the tower base, i assume that will serve the same purpose?

I took the grounding wire off the tower and ran a radial out to the end of my property under the sod (about 4 inches down). Should I run a few more of these in different directions? The tower is right next to the house, right now i have one coming out perpendicular to the house should I put 2 more 45 degrees from the first one. Kind of like this?

```
_________house____________
A <--tower
/ | \
/ | \
/ | \ <--- buried radials
/ | \
/ | \
/ | \
```

I'm putting a metal hose clamp on the tower to keep the ground wires attached to the tower legs, is there a better option? Should each radial come for a different tower leg, or does it matter since the legs are all attached to the metal base.

thanks for everyone's suggestions

Go to www.polyphaser.com and look at the tech notes. Much of the advice you will get here is in error, some even dangerous. Follow the National Electrical Code and the latest version of the Lightning Protection Code, and you will avoid many problems.

Problems like braid deteriorates rapidly.

Problems like concrete explodes when you run too much current through a conductor imbedded in it.

Again, don't listen to me, read the professional codes.

Jim Kelley wrote:
> But power doesn't propagate.

From the IEEE Dictionary: "power-flow vector - ... power per
unit area *propagating* in the wave." emphasis mine

> Define "contain energy".

I already did, Jim. |V*I| = power. I don't think you realize that there
is a Poynting vector for forward power and a Poynting vector for reflected
power such that their ratio equals |rho|^2. From "Fields and Waves in
Communications Electronics", Ramo, Whinnery, & Van Duzer, section 6.10,
page 350, equation (3). I've been wondering exactly where I got such a
large dose of the wave reflection model 45 years ago. It was from that
book in graduate school and "Fields and Waves in Modern Radio", by Ramo
& Whinnery in undergraduate school.

> Energy is certainly required in order create a wave. But energy is not
> consumed by wave propagation.

Energy can be given up by waves in numerous ways. If the wave ceases to
exist, it must, of necessity, give up its energy. Nothing else is possible
unless you wish to propose Dr. Best's supernatural phantom waves all over
again. Energy given up by a destructive interference event MUST support a
constructive interference event according to Hecht. How many times are you
going to ignore this quote from _Optics_? "The principle of Conservation of
Energy makes it clear that if there is constructive interference at one point,
the 'extra' energy at that location must have come from ... destructive
interference somewhere else." If the phase angle between two superposed
voltages in a transmission line is less than 90 degrees, constructive
interference exists. Therefore, there must exist two other superposed
quantities with a relative phase angle of less than 90 degrees.

> First of all, I have no idea what "pre-existing energy" is supposed to
> mean.

Yes, you do. It is |V*I|, or if you prefer, it's the "propagating power vector"
indicated by the Poynting vector. There is a Poynting vector associated with
a reflected wave. The reflected wave contains energy and momentum. The reflected
wave does not reach the source (in a matched system). What happens to the energy
and momentum in that reflected wave that travels all the way rearward from the
mismatch point back down the transmission line to the match point? Have you
no idea what a rearward-traveling propagating power vector implies?

The 100% perfection in the effect seems to be unique to transmission lines.
Coherent waves in a transmission line are forced to be collimated. EM waves
in free space are extremely difficult to collimate perfectly. That's why
the physics mechanism is not well understood.

> Sure doesn't look like it went the way you said it was heading. It

Of course there's a way for it to turn around. The Conservation of
Energy principle will not allow any other outcome. What do you think
reverses the momentum of the rearward-traveling propagating power vector?

The explanation is covered on the Melles-Griot web page, Jim. You
really should read that web page someday. Here it is for you again:

"Clearly, if the wavelength of the incident light and the thickness
of the film are such that a phase difference exists between reflections
of p, then reflected wavefronts interfere destructively, and overall
reflected intensity is a minimum. If the two reflections are of equal
amplitude, then this amplitude (and hence intensity) minimum will be zero.

In the absence of absorption or scatter, the principle of conservation
of energy indicates all "lost" reflected intensity will appear as enhanced
intensity in the transmitted beam."

What is it about reflected intensity changing direction and joining
the transmitted beam that you don't understand? If the rearward-traveling
reflected intensity energy did not change direction, non-glare glass
wouldn't work.

==========

Leyland, what you got is what you could have expected. The G5RV is just as likely to be of any use on 60m as it is on any other frequency.

The G5RV at any but its design frequency, is just a random length dipole, fed by a random length feedline, of a random balanced line impedance Zo.

The antenna is designed to have the slight advantage of an exactly 1.5 wavelengths long dipole, centre-fed via an exacly half-wavelength long transmission line between antenna and transmitter, operated only at exactly 14.15 MHz. And even there it is not exact because it depends on height above ground, ground conditions, wire diameters and half-dozen other unknowns.

If you want a centre-fed dipole, just erect one which happens to fit into your back yard, feed it via a wide-spaced open-wire line, of no particular length, all the way back to the shack, incorporating a choke balun and a good tuner. You will then have the most efficient all HF band, all direction antenna in the book.

Allow G5RV to drift out of your mind. It may be painful but do it.

On the other hand don't let me spoil your fun. Enjoy your experimenting.

Yes, you said (Pfwd1 + Pref2 = Pfwd2 + Pref1) doesn't represent
a statement of the conservation of energy principle. If you are
correct, you shouldn't have any problem presenting an example
that violates that equation. If you cannot present such an example,
we have a clue that the equation might make a statement consistent
with the conservation of energy principle after all.

Nice diversion. No, you ducked a question by claiming there was only
one other direction for energy to go. How do you know what direction it
would go in if you were not restricted by the constraints of a
transmission line? What equation shows there is a reversal in the
direction of propagation without a reflection?

Answering a question with a question is insufficient proof. Please
provide the vector analysis for this. Thanks.

:-) That is not what I said, as anyone can clearly see from what has appeared on their computers screens. Nor is it the statement I disputed. I said that it is not the Law of Conservation of Energy. You claimed it was. I said that you cannot arbitrarily draw boundaries and expect energy necessarily to be conserved within them. You claim you can. You are wrong on both counts.

Everything I have presented is backed by science, Jim.
There's only one piece of the puzzle still missing and
I am working on it. The Conservation of Energy principle
tells us that the intrinsic energy in canceled waves has
to go somewhere. One of those waves is supported by a
rearward-traveling power flow vector. It's impossible for
you to dismiss that power flow vector as nonexistent.

Apparently, the reason this mechanism is not well known
in optics is the difficulty in collimating two light
beams. But transmission lines force coherent waves traveling
in the same direction to be collimated. Little by little,
the mystery is being solved. Please stand by.

Doc,

It depends on the type of braid, etc. one uses. The nickel plated is best because it doesn't rust or deterioriate as fast as tin/lead. What I did was clamp some braid to the ground rod, then solder it. After cooling, I sprayed it with clear plastic, and then wrapped it in electrical tape, and then sprayed it again. I used thin heat shrik tubing to protect the braid while the concrete was setting up. I used rebar to strengthen the base too.

Best of luck.

73s,

Evan

That's true for transmission lines unless you know of
another direction of which I am unaware. After all, a
transmission line is essentially a two direction, one
dimensional environment for RF waves.

> How do you know what direction it
> would go in if you were not restricted by the constraints of a
> transmission line? What equation shows there is a reversal in the
> direction of propagation without a reflection?

If it were possible to perfectly collimate coherent light beams,
the result might possibly be a dark hemisphere and a light hemisphere.
I haven't quite figured out what would happen in three dimensions.

> Answering a question with a question is insufficient proof. Please
> provide the vector analysis for this.

Like I said, I'm working on it. Please be patient. There's only
a very small piece of the puzzle still missing but the puzzle
picture is very clear. The reflected power vector exists pointing
toward the source on the load side of the impedance discontinuity
during steady-state but there's no sign of it on the source side
of the impedance discontinuity during steady state. Where does it
go?

It's obvious what happens during the transient state. The reflected
power flow vector shrinks in the direction of the source and therefore
grows in the direction of the load. So how do you explain a power flow
vector that is shrinking in one direction? Doesn't it have to grow
in the only other direction available?

An equation is obviously not the Law of
Conservation of Energy. Resorting to a silly semantaics
argument is just foolish. My equation illustrates an example
of the Conservation of Energy Principle in action. Stated
in words, at an impedance discontinuity in a transmission
line (incapable of storing energy) the total energy flowing
in must equal the total energy flowing out. I notice that
you haven't produced an example proving otherwise.

A reasonable person would be reluctant to lecture to people on a subject with which they are unfamiliar.

> The Conservation of Energy principle
> tells us that the intrinsic energy in canceled waves has
> to go somewhere.

It tells most people that energy does not move in the direction of canceled waves. The only energy involved was transferred there during the transient period. Those oscillations are maintained by the potentials at the boundary without additional energy influx to the line in that direction.

> One of those waves is supported by a
> rearward-traveling power flow vector. It's impossible for
> you to dismiss that power flow vector as nonexistent.

It exists as a mathematical solution that depends upon the validity of the assumption that energy is flowing in that direction. But energy is clearly not flowing away from the load in a matched system. The Law of Conservation of Energy stipulates that when Preflected = 0, Ptransmitted = Pincident. Unsatified with that relationship, you've embarked on an exercise to ascertain how many fairies can dance on the head of a pin.

> Apparently, the reason this mechanism is not well known
> in optics is the difficulty in collimating two light
> beams.

I've already given you a laser example that illustrates what happens when one attains nearly perfect collimation and coherence. Study the Mach-Zehnder interferometer for a single source example. The question which remains unresolved is whether individual waves continue to propagate independent of whether they happen to be in phase or out of phase. We know they do when they're traveling in opposite directions. And we know that photons don't annihilate.

If we assume P3 and P4 were anything other than mathematical constructs, we could just as easily solve the equation P3 + P4 - 2*sqrt(P3*P4) in order to show how much energy is conveyed in the direction of P3 and P4.

> Those joules/sec cannot

No. The equations which underly the Melles-Griot web page show us that our P1 and P2 constructively interfere in order to convey the energy not being reflected by P3 and P4.

> > The interference term "feeds" nothing.

> So you disagree with _Optics_, by Hecht.

I disagree with some of Cecil Moore's interpretation of what is written there.

That's why I have never said such a thing. Under such circumstances I would have said that canceled waves from Alpha Centauri never conveyed light energy to us.

> > How much power does b1 represent?

> None, because all the associated
> energy headed back the other direction, i.e. it changed directions.

I'll agree that b1 equals zero, and that zero energy changes directions.

> Jim, when you, with your high IQ, are incapable of predicting the future?
Good lord, Cecil. With your high IQ, I should think such a "dilema"
wouldn't exist. Energy is transfered through the transmission line to
the boundary during the transient period. At that point the transfer of
energy stops because of the conditions it encounters at the second
boundary. No further energy is transferred into the line, although the
oscillations are maintained on the line (with the energy on the line
being transferred back and forth between E and H fields) by the
potentials that exist at the first boundary.

> Your
> scenario has a large contradiction built in. It not only requires smart waves,
> it requires waves smarter than you, smart enough to predict the future.

There is no contradiction. Only the requirement that the reader has
sufficient intellegence to comprehend the printed word.

> happen in the future at the source.

Energy is transferred until the steady state is achieved, at which point
boundary conditions dictate the flow of energy. The boundary conditions
are obviously different with and without the circulator in circuit.
Your example proves nothing about the flow of energy without a
circulator in circuit.

> For one case, the wave delivers its
> energy to a circulator load. For the other case, the wave delivers its
> energy to the destructive interference event.

We simply differ on how the energy is delivered to the circuit load in
the latter case.

Sorry if my quest for knowledge disappoints you, Jim. You haven't
answered my questions so I am still asking them.

> It tells most people that energy does not move in the direction of
> canceled waves.

Sorry, Jim, but the reflected wave Poynting vector proves that
you are wrong about that.

> The only energy involved was transferred there during
> the transient period.

During steady-state, the reflected wave Poynting vector exists
on the load side of the impedance discontinuity but not on
the source side. Where does that propagating power flow vector
go, Jim? It's easy to see that the disappearing reflected power
flow vector on the source side of the impedance discontinuity is
joining the forward wave power flow vector on the load side.
Otherwise, there wouldn't be enough reflected power to cause
wave cancellation.

> But energy is
> clearly not flowing away from the load in a matched system.

Uhhhh, Jim, we are discussing mismatched loads. Energy clearly
does flow as a reflected wave back from a mismatched load. There's
even a power flow vector associated with it. Please reference
"Fields and Waves in Modern Communications", by Ramo & Whinnery,
section 6.10.

> I've already given you a laser example that illustrates what happens
> when one attains nearly perfect collimation and coherence.

Nearly perfect won't hack it, Jim. A transmission line is a perfect
collimator of coherent waves traveling in the same direction. Your
interferometer is not. Come back when you get your interferometer
adjusted to perfection.

As a fifteen year victim of a large, three-letter telecom company, I
can tell you that they are indeed run by idiots. The current "achieve
profitability by litigation" dust-up in the Linux world was caused by
one of the company's ill-advised sell-off of intellectual property.
The telcos have laid off, retired or driven out any remains of talent
or expertise since 1984 when Judge Greene decided that he could
improve telephone service from the bench. All that are left are
pencil-pushers, bean-counters and clock-watchers. As a WAN engineer
and administrator, I have seen the telcos go from bad to worse. There
are almost 1200 LECs and CLECs in North America and each is as bad as
the next for service and reliability. It's a wonder and a tribute to
the designers that the 'net works as well as it does.

Something which doesn't exist doesn't go anywhere. The fact that it
doesn't exist in the reverse direction allows all of the energy moving
in the forward direction to impinge upon the load.

> It's obvious what happens during the transient state. The reflected

I think that's as good a way as any to describe it. We just disagree on
the mechansim by which it occurs.

No, for a matched system, energy is conveyed away from P3 and P4
toward P1 and P2. In fact, 2*Sqrt(P1*P2) equals P3+P4

>>It certainly conveys energy from the destructive interference event to
>>the constructive interference event just as described on the Melles-

>
> No. The equations which underly the Melles-Griot web page show us that
> our P1 and P2 constructively interfere in order to convey the energy not
> being reflected by P3 and P4.

You are saying exactly the same thing that I said. One more time.
The waves containing P3+P4 are destroyed. The energy in those two
waves cannot be destroyed. That destructive interference energy
changes directions and joins the constructive interference event
in phase in the opposite direction just as explained on the Melles-
Griot web page.

> ... canceled waves from Alpha Centauri never conveyed
> light energy to us.

How did Alpha Centauri know not to put any energy in those waves
nine years ago?

> I'll agree that b1 equals zero, and that zero energy changes directions.

If zero energy changes directions, b1 cannot be equal to zero.
You cannot have it both ways.

>with.

Yes, in law, that's the rules. Being Part 15 equipment, devices such as BPL modems will have to tolerate interference.

As one commenter's notes on the FCC site made clear, such interference is quite likely. Licensed-transmitter signal strengths on the wires carrying BPL are likely to be strong enough to saturate the ADC chips in consumer-grade equipment, thus rendering much of the spectrum spreading useless. I've heard of this sort of problem occurring with a number of ADSL modems, and I expect that BPL modems would be as sensitive.

Unfortunately, what the law says, and what public opinion can demand, may be two different things. If licensed operators start shutting down BPL service over large areas of a city, you can expect a lot of pressure on the licensed services to mitigate the problem, even if the law says it's not the operator's legal responsibility to do so.

There's another interesting little problem in this regard. Amateur-radio regs require that the minimum amount of power be used which can communicate in a specific mode (this is both best-practice and FCC-mandated). A lot of people work very effectively using QRP and QRPp, at power levels which aren't likely to cause interference in nearby consumer-grade equipment.

If BPL becomes a reality, and the broadband noise level increases, amateur operators (and other licensed services) are likely to have to increase their transmitter power quite a bit to punch through the interference. This would be legal (modulo the FCC limits on maximum power in various bands) but it could _greatly_ increase the problems of interference to BPL, DSL, television, radio, telephone, and so forth. From what I've heard, in an urban setting, transmitting below 20-25 watts HF usually keeps you clear of the problem of fundamental overload in TV tuners, while higher power levels can cause this to become a problem. If amateurs have to routinely crank up power to 100 watts or more to "burn through" BPL noise, we can probably expect a lot of increased TVI complaints from our neighbors.

Ratio ad adsurbium:

If I put 1000 joules/second [4.47 amperes rms into Zo = 50 ohm] into a lossless transmission line and only get 1 joule/second [0.141 amperes rms into Zo = 50 ohm] output then by the application of Mr. Kirkoff's laws I will build up an infinite charge [integral of I*dt] in the transmission line.

Obviously, that does not happen! So, in the steady state, in a lossless line the 'guzintas' have to equal the 'comesottas'. i.e. conservation of energy.

Reality:

example: I have two transmission lines; one has Zo = 50 ohms the second has Zo = 100 ohms. They are connected in series creating a mismatched junction [50 to 100 ohms]. The Zo = 100 ohm line has an open circuit for a load.

Then the sum of powers is stated:

Pin[50] - Pref[50,100 junction] = Pin[100] - Pref[open]

Rearranging terms:

Pin[50] + Pref[open] = Pin[100] + pref[50,100 junction].

Converting to Cecil's terminology:

Pfwd1 + Pref2 = Pfwd2 + Pref1 ... Jim Kelly, what's the problem??

The equation is an accurate statement.

Those who like sausages or have respect for the law should not look too closely at how either is made.

Your faith in the law indicates that you haven't looked very closely at how it's made.

Laws are made by elected politicians. An idealist would say that the politicians represent the will of the people. If that's so, then a massive number of people complaining about interference would get the law changed quick as a wink (or the FCC would be made powerless to enforce it). A more cynical and perhaps realistic person would say that politicians are beholden to the special interests that fund their campaigns. Consider the relative contributions from hams and from the people making money from BPL, and figure out which way the wind would blow (it doesn't take a weatherman). Either way you look at politicians, you're outvoted, and the law is toothless.

Sit back, munch on a hot dog, and think about it.

What are the groups thoughts on an off center feed antenna being 41 feet long on one side and 96 feet long on the other side. The feed point is a 4:1 balun and then any length of coax to the tuner. How is it for a comprimise antenna for all the bands 80 meters to 10 meters ? Saw this design instead of the more normally seen lengths.

Reg, Not sure why you hate the G5RV so much. I have several friends using them on 60M with low SWR!

I have had many antennas and the G5RV is sure the most versatile. I have had great luck with a common feed dipole for 80 40 20 and 10. Just takes a lot of wire and 40 and 80 are not broad banded enough to cover their whole band!
The antenna you describe will be directional on many frequencies. It will have lobes all over the place on any thing but the resonate frequency and it will have two major lobes. But the G5RV does the same thing!!!!

But the kicker for you is, you don't know whether the circulator is in the circuit or not so your waves don't know whether to carry energy or not. What if the waves arrive without energy just as the circulator is switched in? Bingo, instant violation of the Conservation of Energy principle.

What you need to do is tell us exactly how the reflected power flow vector gets turned around at the match point. Until you do that, you haven't contributed anything of value.

> I think that's as good a way as any to describe it. We just disagree on
> the mechansim by which it occurs.

The reflected power flow vector on the source side of the impedance discontinuity during transient buildup to the steady-state at the Z0-match point obviously shrinks as the reflected power flow vector on the load side is increasing in magnitude. That's a double whammy for you, Jim. Where do those power flow vectors go? Obviously as a surprise to you, the forward power flow vector increases by an identical amount. Funny how that works.

Hi Dave,

Please don't be persuaded by Cecil's strawmen. His characterization of my opinion is almost never a good match to the opinion I've actually expressed.

I had some issues with Cecil's broad generalizations. He claimed that the Law of Conservation of Energy from the text books was irrelevant. He claimed that his equation was the Law of Conservation of Energy, when in fact it was simply an expression for what goes in equals what comes out - an equality. The Law of Conservation of Energy, as stated in the physics books pertains strictly to closed systems. The fact that energy is conserved in his particular open system is not the same thing as a law which observes that energy must be conserved in any closed system. However he's changed his use of the terminology since then, and now correctly terms it an expression of the conservation of energy principle - which is basically how I characterized it in my original assessment. It is simply a restatement of the very same law I cited for him. But he refused to acknowledge that. His argument was akin to arguing that V=I*R is a different law than R=V/I.

As you must know by now, Cecil does not usually allow himself to admit to errors - no matter how small they might happen to be. He's tallying newsgroup points, and that's primarily what matters to him in these discussions - apparently.

More below.

Dave Shrader wrote:

> a load.

Except in the case being examined the 150 ohm line looks into a
reflection coefficient indicating that there is a load of 450 ohms on it
(rho=150/450=.25). That impedance is the one to which the 50 to 150 ohm
transformer provides a match. A match is achieved when rho of the first
boundary equals rho of the second boundary. The net effect of the two
boundaries is that no energy is reflected from the load. Cecil and I
are interested in what occurs between the boundaries, but we've come to
different conclusions about that. I've been chastised for having a
similar opinion to some experts in the field.

>
> Converting to Cecil's terminology:
>
> Pfwd1 + Pref2 = Pfwd2 + Pref1 ... Jim Kelly, what's the problem??
>
> The equation is an accurate statement.

Obviously the equation is accurate. That doesn't mean it should be
abused, however. The point is that the values he uses in the equation
in this example are not useful in an energy analysis. He's right that
the energy impinging upon a lossless discontinuity will net zero. And
it does that with the correct numbers as well. But he shows 50 watts
being reflected, and then struggles to explain how it gets redirected
back toward the load. The answer is simply that that amount of power is
NOT reflected in the first place. Wave cancellation prevents the
reflection of energy. In reality the first boundary has 100 joules per
second impinging on it from the left, and 100 joules per second
traveling through it toward the load. One hundred joules per second
then pentrates the second boundary into the load.

Cecil is interested in constructing an analysis in such a way that one
can sum all the calculable power numbers. I think it's a worthwhile
endeavor, and he does manage to make the numbers add up. But one has to
make a couple of leaps of faith in order to do it. My humble,
reasonably well informed opinion is that it's not justified in the
physics. The fact is that since interference does play a role, one can
only use those numbers by observing phase and using them as terms in the
proper irradiance equations.

P3 + P4 - 2*sqrt(P3*P4), and P1 + P2 + 2*sqrt(P1*P2). The same thing can be shown by squaring the respective voltage terms without necessarily obscuring the phase information. No violations of physics or engineering. No violations of the wave reflection model, no obscuring of phase information, and no leaps of faith. For that, I am characterized as the antichrist.

Modeling a G5RV with EZNEC on 5.368 yields a 50 ohm SWR of 27:1
on the 50 ohm coax. That's not good. The SWR on the 300 ohm
twinlead is OK at 5:1 but the 102 ft dipole is relatively close
to resonance on that frequency and the "matching section" mismatches
the antenna worse than if it was fed directly with coax.

Looking for the best 20m vertical antenna design; without radials or buried ground wires. There is no restriction on the antenna height; except, that I would like to support the antenna at its base and mounted on the roof. I am more concerned about a design that optimizes the antenna efficiency and provides a low angle of radiation rather then for a 50 ohm impedance. The ground is basically sand, not much conductivity.

Any Ideas?

Thanks.

Roy:

The problem is modeling the car, not the antenna. No two cars, even identical models, act the same on the range. Too many metal pieces with uncontrolled contact characteristics. So, one may easily have more horizontal content than the next. Since neither H nor V content is very much.

A few more switches than what I like. Took down the antenna farm while building new garage/workshop/ham shack. When project is completed antennas go back up. Will probably use the two antenna approach since shack will be right at the base of the tower and it will not have a lot of room for the phasing sections. I do like you r aproach though. If I didnt live in this yuppie neighborhood I would probably try it.

Could I get some input on whether it would be prudent to paint my 2-meter copper tube j-pole or not? I've been told that copper oxide actually increases the gain of the antenna, but I don't know if that gain is enough to outweigh the benefits of painting it...

Altenatively it could be said that he is a gentleman, never takng the bait and lowering himself to the gutter like many (including myself at times) in this newsgroup.

A man who seeks to encourage others into the hobby, and seeks only to share the enjoyment that he has had in the last 20+ years with others.

He has no fear of progression, and meets it head on. He is not stuck in the past like many others.

He is the kind of "face" that Amateur Radio should have, a welcoming friendly one. There is very little of that to be seen in this newsgroup.

Regards,

Alan

Nope. Off the top of my head. Result of years of
technical improvement in the Ham tradition.

In any case, I don't use the Web due to the cost of the
phone calls.

Suggest you change your CB habit (apparent from the
silly childish remark below) and look at becoming
a Ham.

Leyland, You got me all wrong!

I don't in the least hate G5RV's. (Note the plural). All are fascinating.

I just can't understand why they are religiously worshipped by so many (millions) of followers.

I have several friends who *don't*. ;o)

Remove the coax to make a true G5RV, and taking together the whole collection of bands, wire-diameters, heights, line Zo's, design-frequencies and superimposed radiation patterns, the G5RV is indistinghishable from any other dipole taken at random from the pile.

Here's another interesting fact. If the impedance of the 1/2-wavelength feedline is changed from 300 to 450 to 600 ohms you will have three altogether different sets of resonant frequencies and line input impedances. But you will still have a G5RV working as Mr Varney intended on 14.15 MHz. Take your pick.

I now (8th July, 2003) propose another simple multi-band, multi-direction without rotating, antenna.

It's a 142-feet dipole, fed via a balanced line of any impedance which is 1/2-wavelength long at the anenna's design frequency of 10.1 MHz. It will go like a bomb on the 30 metre band with a lovely clover-leaf radiation pattern. With a tuner it will work very well at other frequencies between about 2.7 and 30 MHz.

If interested use program DIPOLE3

Source record: 113205

>> Looking for the best 20m vertical antenna design; without radials

>center fed vertical dipole >gap is one, I think

I have a friend (OE3TL) that has *tried* the GAP. Actually its a
top-feed dipole. We had to put this 'christmas-tree' up and down
several times, because the SWR was out and away.

So I decided to buy a hy-gain AV-640. The concept is new and unique,
the AV-640 uses vertical stubs, there is nothing to get 'wet' and
nothing that can be burned out etc. The subs are more slim and the
construction is not as 'christmas-tree-like' as the GAP is.

My experience with the AV-640:

- you need guy rope in 14ft from the base. Any antenna needs this,
because it's a mechanical illusion to have an antanna of this size and
construction without supporting ropes.

- replace the hose clam with 'real ones' (I have pictures on this)
- send me an email to oe1mww @ qsl.net (remove the blanks!) and I will
send you pictures how we built it - and will answer your questions

I can't be bothered to look Walt up but I'm in the book
and I suspect he is. The full name and callsign tend
to imply somebody who stands by his opinions and is
prepared to own them. I may disagree with him at times
but at least he doesn't hide who he is.

Please don't be persuaded by Jim's strawmen. His characterization of
my opinion is almost never a good match to the opinion I've actually
expressed.

Jim has painted himself into a technical corner and cannot explain why
the reflected power flow vector changes directions at a Z0-match point
so he, as typical for him, resorts to ad hominem attacks.

> I've been chastised for having a
> similar opinion to some experts in the field.

No, you have been chastised for having a different opinion from
some experts in the field, namly Johnson, Ramo, Whinnery, Hecht,
and Melles-Griot.

> But he shows 50 watts
> being reflected, and then struggles to explain how it gets redirected
> back toward the load. The answer is simply that that amount of power is
> NOT reflected in the first place.

We know that the reflected power flow vector gets turned around at a Z0-
match point. How does the reflected power flow vector get turned around
if the energy is not reflected? To where does the reflected power flow
vector flow if it doesn't turn around? Wave cancellation obviously turns
the reflected power flow vector around.

Jim, if you are talking about your answers with all those contradictions, they are obviously technically incorrect. You haven't even explained why the reflected power flow vector reverses direction.

> Obviously you need to explain how a vector get turned around in the
> absence of a reflective surface, seeing as your entire argument hinges
> upon it.

Wave cancellation between coherent wavefronts traveling in the same direction turns the reflected power vector around, Jim, just as explained on the Melles-Griot web page. What is it about 'lost' rearward-traveling reflected energy joining the forward-traveling beam as enhanced intensity that you don't understand?

>>Where do those power flow vectors go?
>
> I have no idea what that's supposed to mean.

That's obvious, Jim, and it's really sad. Vectors represent things with magnitudes that move in the vector direction. The vector direction of the reflected power flow vector reverses at the Z0-match point. I have presented an explanation of why. Walter Maxwell has presented an explanation of why. All you have presented are some arm-waving mantras which contradict the laws of physics.

> I can't think of any other way for it to work, so it's not surprising to
> me at all.

You say you are not surprised that the reflected power flow vector reverses direction at a match point. How does that happen without the energy in that power flow vector changing directions?

> Sounds like a typical 'OCF' for 80 meters, except
> for the balun. Wonder why they want to use one?
> 'Doc

It is a OFC antenna for 80 meters. I ran across an artical on the internet a while back and forgot where it was. From what I remember the feed point was moved some from the normally used point to get something closer to 200 ohms instead of 300 ohms so that a 4:1 balun and coax could be used instead of feeding it with open wire feed line. I know it is a comprimise antenna but was thinking of putting one up at a place where the supports will be in the correct place to run the feedline a shorter distance than if I use a center fed dipole . I also want to run more than one band and not use the open wire feeders. The antenna is for a temporary location. I have not done much work with the low band antennas as most of my work has been with weak signal VHF and above.

What I am looking for is a simple antenna without traps that will allow me to keep a sched on 80 meters with a friend while I am away form home and also have the ability to use other bands without a big loss in efficency and be coax fed. I know I could just use a 80 meter dipole but would be taking a big loss on 40 meters if I use coax to feed it.

>

I have the same problem with the J-pole VHF antennas. I just don't understand why they are worshipped either. Sort of reminds me of the old Ringo antennas when I first got started in ham radio in the 70's. Not much antenna but most everyone was using them, same as with the 11 element CC antennas.

I don't do the low bands much but have read that one of the best antennas for multibands was to take about 280 feet of wire (1 wavelength at 80 meters) and put the ends as far apart as you can. then bring what is left of the wire in the shack by making it into an open wire feedline. For someone that cares about the low band antennas it might be a good project to change the length of the antenna portion of the wire vers the feedline portion.

The isn't the amateur bands so callsigns are not needed. Who knows if you
are really Walt Davidson who holds the callsign you use?

You can find Gareth's details in Google, if you care to look. I am sure the
real Walt Davidson's are on one of the roll of elector CDs.

It seems to be perfectly good English, correctly spelled (spelt?) and in no way abusive. It expresses an opinion which you may (almost certainly will) disagree with, but there are plenty who will find it very valid... You seem to be very ready to make your own subjective judgements of others but have great difficulty accepting their right to make their own of you.

When we find out who you are, it will be an interesting exercise
to present your profile to the Law Society.....
Either.....
1. You are making a false pretence as to your status as a legal
professional, in which case the law, let alone it's Society, will
be after you.
or.....
2. Your childish and insulting outbursts, ("shows promise as
dog turd)"? given virtually in the same breath as you pretend
to be a legal professional are bringing the legal profession
into disrepute.

<Snip>>
> Well, I sorta disagree for pretty much the same reasons as Roy. The
> patterns , unless distorted by the car body, will not change very much
<snip>

Exactly. The patterns are highly dependent on the uncontrolled car body conductivity. Modeling the antenna is secondary. Modeling the car body is impractical, except in a general sense, because no two even identical models from the same production run, are alike at RF. So, the shootouts are often a comparison of two automobiles, rather than 2 antennas. If you want to compare antennas, mount two of them butt to butt as a dipole with a 1 watt transmitter at the joint, hang them from a blimp, and measure the far field. Then you are measuring antennas. Otherwise, the car rules.

>Well, being most all mobile verticals are not really well suited for
>NVIS type operation, there should not be too much high angle
>radiation, unless the pattern is distorted by the car body

So, very minor changes in pattern make big changes in the usable signal. You are making the point for me, and are not looking at what you are writing. "Unless the pattern is distorted by the car body" My observation has been that every mobile antenna article starts by stating that the car body is the controlling factor in the pattern which you can't control.

I would say a vertical 1/2 wave dipole. If you can hang it off a tree branch from the top, and run the cable off at 90 degrees, the price will be almost free.

686. Re: Feedpoint impedence / wire diameter

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-08 14:11:17 UTC
From: John Passaneau <jxp16@psu.edu>
Message-ID: <beeje1$vn2$1@f04n12.cac.psu.edu>
Source record: 113131

Hi Jeff,
The best way for you to find the answer is to down load the demo version on EZNEC and try it your self.
But I became interested and modeled it myself.

On 7.15MHz, a dipole at 30' over average real ground, with each leg 401.75" long has a Z of 63.4+J0.7338 Ohms with #14 wire. Changing the wire to #10 changed the Z to 63.14+J2.817 Ohms. This means the resonate frequency is lower. By shorting each side by 0.53" to 401.22" brought antenna back to resonance at 7.15MHz with a Z of 62.98+j0.7913 Ohms. Changing the wire diameter from #14 to #10 lowered the resonance frequency, which took a 0.53" shorting of each leg to bring it back to 7.15MHz and lowered the real part of the impendence by 0.32 Ohms. This is because with the larger diameter wire the RF resistance went down. As the loss with the larger wire went down, the gain of the antenna went up from 7.97dbi to 8.01dbi a change of 0.05dbi. The bottom line at 40m changing the diameter of the wire makes a very small change which would not be visible with typical ham SWR meters or antenna analyzers.
The effect of changing element diameter becomes more pronounced as you go higher infrequency. At VHF/UHF the effect is very noticeable.

Hi, All.

I've been reading several web pages about the construction of copper pipe J-pole antennas for 2 meters, and they're all quite similar, with one exception: some say to connect the coax center conductor to the stub, and others say to connect the coax shield to the stub. Is one preferred over the other? Does it matter?

Thanks and 73.

-Bill

A coaxial dipole (coax feedline runs down through the center of the
hollow lower element).

It shouldn't make a difference since the feedpoint is balanced with
respect to ground.

693. Dipole Help

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-08 14:48:36 UTC
From: whitehat <rpav@suffolk.lib.ny.us>
Message-ID: <9WAOa.270$603.15164@iad-read.news.verio.net>
Source record: 113137

I recently bought some surplus ham equipment to get
started in the hobby and it came with the beginnings
of a dipole antenna but I don't know what band it is
for and what I need to finish it. Here's what I have:

From the center insulator there is 22 feet of wire
on each side that terminates on a plastic insulator
board. There is a one inch gap and then another 22 feet
of wire to the end insulators.

Some help?

Lot of people don't provide calls on Usenet, for some reason.
Anybody that provides a real email address must LOVE SPAM.
And if you look at the message headers from Mr. Bean, you
may be able to figure out why he's not in the FCC database.

What I can't figure out is why we need to crosspost this stuff
to five different newsgroups.

Would you be more inclined to agree with Mr. Bean if you
knew his call, where he was, and his email address ?

==========

Jeff,

Download program DIPOLE3.

Enter any dipole and feedline length, etc.

Change antenna wire diameter and see immediately what happens to dipole
input impedance.

But changes are negligible unless diameter is increased by 10 or 20 times
depending on what you start with.

Program takes into account conductor resistance in addition to changes in
inductance and capacitance of the wire.

Does anyone have some experience with
the Ringo Ranger II?
I just got one for free and I can not
make it work well. The SWR is 1.15 or
thereabouts at 147.800. At approx 145.800
it would be about 3.0. I am not getting
any signal out to the nearby repeater, but
I can hear it full loud and quieting.

Irrelevant.

Ham Radio is a technical pursuit for those suitably
qualified and motivated. Ham Radio is not about Cheque
Books (CB) nor Childish Blurtings (CB). Ham Radio is not
the business of operating radios without knowledge of their innards
nor the capability to modify and maintain the innards. Such
a pursuit is known as Citizen's Band.

In the context of this thread, what is the difference between the
Yank CBer and the Yank "Radio Ham"? Nothing at all, it
would seem.

Is the style and language of the posting quoted above that
which is to be expected from someone who pretends to
be a radio amateur?

Hi!

What kind of antenna can i use with a tranciever (Albrecht AE 485 S) in the 27-28Mhz (10 m)?

I tried an 27Mhz mobile antenna, but it can not be adjustet under 3 on the SWR-metre.

/Mikael

Gareth,

Easy on the use of the word "Yank". Especially if you've never lived here.
I've always hated the use of that term by the "Blokes", especially when I
lived in England.

Cecil, W5DXP wrote:
"How does the reflected power flow vector get turned around if energy is not reflected?"

At the shorted receiver, the voltage wave is reflected, out-of-phase with no change in waveform.

Current is reflected, in-phase with no change in waveform.

Practical transmission line work has no use for instantaneous phenomena.

There are three voltages of interest on a transmission line, forward, reflected, and the vector sum of the two.

The vector sum produces VSWR.

The reflection coefficient is the ratio of reflected voltage to forward voltage.

Forward power is the average energy flow rate toward the load.

Reflected power is the average energy flow rate back toward the transmitter.

It`s possible to have a forward power of 300W, a reflected power of 100W, and a power from the transmitter, and delivered to the load, of 200W.

With termination in an open or a short, equal forward and reflected powers are possible with zero watts delivered by the transmitter or delivered to the load.

With a termination which equals Zo, there is no reflected power. All the transmitter power is delivered to the load.

At the junction of dissimilar (different impedance) transmission lines which appear as a Zo match on the transmitter side, but as a mismatch on the second line`s side of the junction, there is no reflection toward the transmitter, if we adjust properly. There is no reflection toward the transmitter because it appears as Zo.

On the second line`s side of the junction, there must be a reflection, otherwise it could not present a match to the transmitter side of the junction.

The reflected volts in the second line side of the junction must be of magnitude and phase to adjust the impedance presented by the line to the first line`s Zo.

A half-wavelength of any Zo repeats the Z of its termination at its input. Its ends exhibit reciprocity.

The reflected voltage arriving back ai the input of a !/2-wave line input would be the same at any number of 1/2-wavelengths. At 1/2-waves back from the load, waves would pass right through each other. But,there is a difference at the cable junction. It`s a discontinuity and at discontinuities, reflections are possible. No reflection on the transmitter side, tells us that the reflection on the load side of the junction is a re-reflection which stands-off the assault of the reflected wave.

The re-reflection doesn`t just reflect the same percentage of energy reflected at the load end of the line, it reflects it all because none of the reflected wave makes it through the junction to its transmitter side.

What`s different about the transmitter end of the line between the junction and the load is that the power is coming from the transmitter end. The reflected volts can be phased to rise and fall in-synch with the forward volts. The reflected volts are always inferior to the forward volts. There is no way inferior in-synch volts are going to coerce current against the stream.

At a discontinuity, you have a difference in abilities of dissimilar transmission lines to generate counter-emf, to hold charge, and a difference in the ratio of these abilities. This can make a reflection.

Best regards, Richard Harrison, KB5WZI

It looks like it is resonate too high in the band. Make sure the lengths of the elements are set correct and maybe lengthen them slightly (maybe an inch or two).

YOu probably got it for free because they do not work very well. They tend to act like a long wire and radiate most of the signal up instead of out.

watt
>transmitter at the joint, hang them from a blimp, and measure the far
field.
>Then you are measuring antennas. Otherwise, the car rules.

They are not comparing only antennas. They are comparing antenna
systems.
As I said before, if the car bodies are a major issue, mount all the
antennas on the same radial system, on the ground. Besides, the
performance of most all short verticals is already known. No need for
the blimp exercise, unless you just want to verify what is already
known.

>Well, being most all mobile verticals are not really well suited for
>NVIS type operation, there should not be too much high angle

>writing. "Unless the pattern is distorted by the car body" My

observation
>has been that every mobile antenna article starts by stating that the
car
>body is the controlling factor in the pattern which you can't
control.

But "MY" car body is controlled. If I keep the same mount, but change antennas, comparison tests between the different antennas is quite valid. And if I change my antenna, the only thing that will change is the efficiency. The pattern is not going to change much at all, even if I add 3 or more feet to it. Now, if you want to compare my "system" to another, then yes, the results will be skewed to the the difference of the other car body, but I think most of us accept this.
Life ain't perfect. But I still stand by the general statement that changing short mobile antennas on the same car body, does not change the pattern much at all, only the efficiency. If NVIS operation is important, do A/B tests from a distance also. Of course, to do this will require a reference antenna to compare to, to allow for propagation changes. On "my" car with my antenna, if I increase the performace at one angle, I'm increasing it at all others being the only real change is efficiency. So as far as comparing antennas all mounted on my same truck, the "shootout" results should be quite accurate. Being as most all the others antennas and bodies will act the same, when comparing car against car, yes, the body will make a difference, but myself, I can accept this. We are comparing the complete systems. Many try to improve the ground systems/car bodies as part of the overall system. I know I did. It's part of the "test".

Theory says it should not mater but in practice most get beter results if the longer leg is connected to the center conductor of coax. YOu really need a balun at the antenna but most do not use one. A simple loop of coax connected for a balun makes them work beter.

Some folks say that it doesn't matter at all.

Some folks say that you get a slightly broader SWR bandwidth if you
connect the center conductor to the radiator and the braid to the arm
of the matching stub.

I suspect that the presence, or absence of a choke balun will make
more of a difference in the antenna's pattern and performance than
which wire you hook up where.

Naturally, it sounds like you want a 1/2 wave vertical. You can easily
build one. Will be about 32 ft tall. You can base feed it with a
"gamma loop" type feed system. I think this would be easier than
trying to split the radiator , and center feeding. The "loop" for that
antenna would be appx 22 inches across, and a single turn. You can use
a piece of coax for the capacitor. You tap the coil for the best
match. This is the same feed system used with many of the cushcraft
verticals. You can see details of these in the PDF files on their
website. They are easier to get going than it sounds, and if you mount
the antenna up well off the ground on the roof as you say, it will
kick butt over most any "storebought" 20m vertical. BTW, in your case,
a horizontal dipole should work well also if it's high enough to
provide the low angle performance you want. It's overall efficiency
should be greater than most any vertical, unless measures are taken
for the vertical. But, none the less, the 1/2 wave vertical will work
well. MK

Go here at get a manual for it.
http://www.cushcraft.com/support/pdf/951290.pdf
The adjustments for 145 mHz and 147 mHz are different, so I imagine
you will have to pick the area you want to operate in.

Depending on the distance from which you want to receive Navtex, a simple
antenna should be sufficient for Navtex in the region where you are sailing.
You might want to use a simple vertical wire, possibly connected to your
receiver with an MLB.
Please note however that Navtex is broadcast on 518 kHz.

Hello: I have FOR SALE: two BRAND NEW, NEVER OPENED ProComm 40 meter mobile antennas. (These are VERY similar to the Lakeview HamSticks.) Also...a BRAND NEW, NEVER USED Lakeview Dipole Mount. Together, these make a portable dipole antenna system. You can mount either vertical or horizontal. Needless to say, you can order more antennas from ProComm or Lakeview to get you on other bands. I'll even toss in some coax. I've been bitten by the 2 meter sideband bug, and am just not up to any HF operation right now. $39 takes it off my hands. I'll even pay for the shipping. 73 from Bill, WA8MEA

I am using a homebrew dipole (is there any other way?!) and it works quite well. Although I cannot transmit and propagation qualities are waning, I pick up quite a few conversations from where I am in eastern Va. (Fla. and West Virginia and some spanish chatter as well.) I used 28.475 as the freq for the math. I am using an htx-10 with the antenna in the attic and get 1.5:1 on 29.699.

Hi John!

Thanks for the input and insight. I've seen EZNEC but never gave it
thought! Something to add on the to-do list. :)

I was under the impression that it would lower the impedence by
increasing the diameter and if I read it correctly, I was right.

Changing the element diameter at.....slightly above UHF, microwave
is what I'm after. I'm in the process of making a helix for a passive
reflector for an , UO-11, AO-40 test setup and was debating whether to
use #*8 ground wire or 1/4" refridgeration tubing for the conductor.
I've been leaning towards the tubing since I made one a couple years a
go for the fun of it and it's durable, rigid and keeps its shape. Now
added to itm lower RF resistance and impedence as well.

725. Tuner ground length question

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-08 20:34:27 UTC
From: Ron <rons533@dejazzd.com>
Message-ID: <3F0B299B.543A@dejazzd.com>
Source record: 113069

I would like to get on 10-40 meters.
I plan to put up a random length wire fed to an MFJ-941D tuner. The problem I see is that it is 20 feet to my closest ground. I plan to use 1" copper strapping from the tuner to my ground which is 2 - 8 foot ground rods driven into the ground spaced 10 feet apart outside my shack.
Is this too far for my ground connection?

You're speaking of this "energy" as if it has a life of it's own. Very imaginative. But very wrong. Please don't lecture any further on this subject until you learn more about it and take a few tests to verify you've learned it correctly.

It made the decision not to send energy at the same time it decided to send the two beams to us out of phase.

> > I'll agree that b1 equals zero, and that zero energy changes directions.

> But the kicker for you is, you don't know whether the circulator is
> in the circuit or not so your waves don't know whether to carry
> energy or not.

Your understanding is severly limited, Cecil. It's really to the point of not being able to carry on a cogent discussion on the subject. Your problem with the subject is this idea of yours about "carrying" or "possessing" energy. That they "have to decide" something or other. It really is ludicrous. You're going to have to come to the realization sooner or later that the problem is on your end, not everybody elses.

> What if the waves arrive without energy just as

Melles-Griot never said that. No one but you has ever said that. There
is absolutely nothing in physics literature anywhere that says that.
And you cannot prove mathematically that it's true. It's not true!!
Give it up. You're wrong. It's utter and complete bullcrap - on every
level!!

> > I can't think of any other way for it to work, so it's not surprising to

I need to make a balun that requires the use of 300 ohm type twin feed but the narrower spaced 120 ohm version.

This wire is pretty hard to find, there may be a German manufacturer.

Anyone have any idea who makes this stuff? I need quite a large quantity.

Thanks

Joel

So, you feel that out of phase light waves of equal amplitude, "will
burn a hole through black paper." I hope I've quoted that correctly.

How do you feel about those waves and white paper? Maybe they pass
through and then turn around and come back the other way? Or maybe
in-phase waves burn holes in white paper, and out of phase waves burn
holes in black paper?
Whatever it is, I'm sure you have it all figured out and will soon be
lecturing about it at physics colloquia all over the country. ;-)

A couple of thoughts, ordinary zip cord has an impedance around 70-100 ohms, check the impedance of 2 conductor speaker wire sold at various places it might be close to 120 ohms. You can take 300 ohm twin lead and carefully heat the plastic between the conductors, bend into a "U" configuration, and decrease the characteristic impedance.
I have never heard of 120 ohm line, but there are several things out there that can get you in the ballpark.

> waves that engage in total wave destruction are conserved.

In the laser bench experiment I discussed, we had two lasers and four waves (two orthogonal pairs), but with more equipment the same thing could be done with a single laser. When one beam pair destructively interfere, the other pair constructively interfere. All of the light energy is conveyed along the path where the beams constructively interfere, and none of it is conveyed along the path where the beams destructively interfere. Energy does not physically go first to the destructively interfering pair and then over to the constructively interfering pair, as you claim the Melles-Griot web page tells you. All of the energy is conveyed directly by the two constructively interfering pair of beams.

Uhhhh, Cecil, your paper says matched system. So, that's what I'm talking about. Do you want to change the subject?

> > I've already given you a laser example that illustrates what happens
> > when one attains nearly perfect collimation and coherence.

> Nearly perfect won't hack it, Jim.

Of course it does. It demonstrates exactly what happens to cancelled waves, and what happens to waves which reinforce, as well as what happens to the tiny portions which are absorbed, or which don't precisely overlap. Everything is right there and can be measured.

How far away are the stations you work on 75 meters mobile? Did you really think you were generating ground waves that went that far? Do the math.

do A/B tests from a distance also. Of course, to do this
> will require a reference antenna to compare to, to allow for
> propagation changes. On "my" car with my antenna, if I increase the
> performace at one angle, I'm increasing it at all others being the
> only real change is efficiency. So as far as comparing antennas all
> mounted on my same truck, the "shootout" results should be quite
> accurate.

But that's nort how it is done, generally. Sure, some try more than one antenna, but often entries are limited to one shot due to time constraints. I never said comparing antennas was invalid, only comparing totally different systems with undefined parameters and then blaming/praising only the antenna.

Being as most all the others antennas and bodies will act
> the same, when comparing car against car, yes, the body will make a
> difference, but myself, I can accept this. We are comparing the
> complete systems. Many try to improve the ground systems/car bodies as
> part of the overall system. I know I did. It's part of the "test".
> MK

But then, you give the credit only to the antenna, and don't mention improving the rest of the system? So if a relatively poorer antenna on a good, well prepared automobile (or a Suburban with a 20 foot flatbed trailer with several 1" braids supplementing the trailer hitch) produces higher measured field strength than a better antenna on a poorer mounting choice, like a tiny car for an extreme example, then the poorer antenna is better? That's what your "shootout" will show. Shootouts are good ego boosters, but show relatively little about individual antennas. I didn't say antenna systems, I said antennas, which is what the original inquiry was about. Now, if he had asked about improving the platform and system, then that's additional material. Start with the biggest, lowest vehicle you can find, add copper straps,.....

"None of the reflected wave making it through the junction" is not a
cause. It's an observation. Why does none of the reflected wave make
it through the junction? Why is all the reflected power re-reflected
at a match point. You have observed what happens. You have not offered
a cause for what happens.

It didn't make that decision, Jim. On earth, we split the light from
Alpha Centauri into two beams. So Alpha Centauri has to be able to
predict the future 9 years ahead of time. Your assertion is ridiculous.

>>If zero energy changes directions, b1 cannot be equal to zero.
>
> Perhaps in Ceciland. :-)

If the reflected power flow vector from a mismatched load doesn't change
directions, it will become incident upon the source. We know it doesn't
do that. ERGO, it changes directions (or falls into some supernatural
black hole of your invention).

I agree, but that is the inescapable conclusion at which we must
arrive if what you say is true. Your waves carry energy or not
depending upon a random future event that even you cannot predict.
Your waves are necessarily smarter than you are, Jim. This is
exactly how you have described them. You waves are as smart as God.

Yes, they did, Jim. Here it is again direct from their web page:

"If the two reflections are of equal amplitude, then this amplitude
(and hence intensity) minimum will be zero. ... the principle of conservation
of energy indicates all "lost" reflected intensity will appear as enhanced
intensity in the transmitted beam."

What is it about the rearward-traveling reflected intensity in the
canceled waves appearing as enhanced intensity in the forward-traveling
transmitted beam" that you do not understand?

Before they cancel, they will each burn a hole in black paper, proving
that they contain energy. After the two waves cancel, their intrinsic
energy must go somewhere. Energy cannot be destroyed (by ordinary means).

This is nothing like a transmission line because there is no wave
cancellation. Why even bring it up? You continue to confuse normal
interference patterns with wave cancellation.

I once measured some zip cord at around 100 Ohms. If you have any way of measuring it, you could try several pieces, and see if any is close to 120. Probably 18 or 20 wire would be the best bet. I have seen 120 Ohm coax, but very expensive.

> Why should someone believe you when you haven't provided any proof?

Good Lord, Jim, I am not about to attempt to teach Poynting vectors
to you. Having to teach you about s-parameters was bad enough. May
I suggest that you read a book?

> Uhhhh, Cecil, your paper says matched system. So, that's what I'm
> talking about.

You are confused, the system is matched but the load is mismatched.
The reflected power flow vector flows away from the load when the
load is mismatched whether the system is matched or not. The conditions
on the line feeding a mismatched load are the same whether the system
is matched or not. Your failure to comprehend that fact is one of the
many things wrong with your argument.

>>Nearly perfect won't hack it, Jim.
>
> Of course it does. It demonstrates exactly what happens to cancelled
> waves, ...

No, it doesn't, Jim, and your failure to comprehend that fact is one of
the many things wrong with your argument. "Nearly perfect" demonstrates
normal interference without wave cancellation. 100% perfect wave cancellation
is a different event in which the waves cease to exist.

> arrive if what you say is true.

Waves that propagate to a dissipative load transfer energy to that dissipative load. Waves failing that test fail to transfer energy. Reflected wave V4 doesn't propagate any further than the first boundary. It conveys energy (to the 150 ohm transmission line) during the transient period because it has yet to be cancelled by V3. V3 conveys energy to the 50 ohm transmission line during the same period of time, but doesn't propagate after that. At that point neither wave transfers energy due to cancellation. V4 does not convey energy beyond the point at which the waves are canceled. V3 does not propagate beyond (or back from) the source. No further energy is conveyed in the form of these waves. Their oscillations continue on the line, stimulated by the respective boundary potentials. But unless the boundary conditions change, these waves do not have a mechanism by which to convey energy to a dissipative load, and their path is truncated. The effect of V3 can indeed be seen on V1 because the field oscillations are nevertheless maintained by the potential at the first boundary. But since no energy is output by these waves, no additional energy is input to them. All of the energy conveyed from source to load is accounted for by the superposition of V1 and V2. We can see exactly how that occurs by studying the irradiance equation, or more specifically the field equation for constructive interference. Those are the only waves which propagate and convey energy in the direction of the load. Reflections from boundary one are cancelled by reflections from boundary two, and in doing so the reflection of energy from both discontinuities is prevented.

Listen for us on 28.435 every day at 1:00pm
Eastern Time. Now 1700Z in the winter months
1800Z. Seven days a week. It is a good way to
check propagation, and work Delaware if you need
it. There are six to 10 regulars that can use
ground wave between each other, so we meet. If
there is an opening please join in, with the
proper license of course.

Attach at least one wire two the ground rods a
quarter wave length long at the lowest frequency
you plan to operate. You also need to check, but
your local electrical code may very well require
that the ground rods be "bonded" the household
electrical system's ground.

Verifying that indeed, Melles-Griot didn't say "Wave cancellation
between coherent wavefronts traveling in the same direction turns the
reflected power vector around".

That you think it means the same thing is only your contention. It is
not, however, a matter of fact. The fact that light which is not
reflected would appear in the transmitted direction is obvious from the
conservation of energy law that I cited, given R + T = 1.

750. how to install NMO blind mount?

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-08 23:51:41 UTC
From: k9sqg@aol.com
Message-ID: <20030708195141.28965.00000051@mb-m28.aol.com>

I bought an NMO style mount at Hamvention for a blind hole installation (i.e. no access from the back side to install it). I drilled a 3/4 inch hole and then discovered there isn't enough clearance to slide it in. Anybody have any hints or know of a brand of NMO mount that really works?

73s,

Evan

Oh, before! Yes it's true that a laser can burn a hole in paper. Quite
a telling and profound observation there, Cecil.

> After the two waves cancel, their intrinsic
> energy must go somewhere.

Energy from the LASER does goes somewhere. But it does not go in the
direction of destructive interference. It of course goes in the
direction constructive interference (or non-interference). However it
takes the direct route, rather than the circuitous route you have been
lecturing to us about. It's quite apparent there is no such route. But
you might have to first understand the mechanisms that create such
circumstances in order to see it. If you provide those mechanisms in
your example, I will elaborate.

>
> Yes, that's the missing mechanism that I hope someone will supply.

Until that shows up, it's pretty much a dead on arrival. Is it that you wonder why the transmitted intensity goes up by a factor of four when two equal amplitude waves constructively interfere? I really have lost sight of why you think there's a mystery to be solved here. All you have to do is throw out a couple misconceptions, and you're there. Everybody else was apparently there a long time ago.

> We know that energy cannot be
> destroyed. We know that every EM wave contains energy. Therefore,
> we know that the energy in the canceled waves must go somewhere.

There is no energy being conveyed by the cancelled waves, so no energy is "destroyed" when the waves are cancelled. Unlike you, energy takes a 'constructive' route.

> > There is no path for energy after waves cancel.

> Waves cannot exist without energy. These waves cease to exist at the
> cancellation point.

Well, it seems they don't propagate beyond the cancellation point. They convey energy no further than the cancellation point. But I don't see need of worrying that energy might be destroyed at the cancellation point. I think we pretty much agree that doesn't happen.

> Where does the energy in the destroyed waves go?

It doesn't go. It went elsewhere instead.

> You have asserted that waves that are about to be canceled exist without
> energy, but that is obviously a violation of the laws of physics.

I've asked that you use quotes when you refer to things I've said. You're fabricating remarks, and arguing against them. I think there's a

name for that kind of practice. I have some names in mind, but it would
be less than gallant for me to print them.

> >>If "energy exists only where the waves exist", how can waves exist without

So if you could explain to us the process by which the cancellation occurs, you might then begin to understand why energy can't be conveyed by the cancelled light waves. (Hint: it has to do with conservation of energy.)

Seemed a fair assumption, since you don't account for losses anywhere in the paper. Your power numbers wouldn't add up so nicely if there were losses.
You've got a forward power of 133.33 watts on the 150 transmission line, and 33.33 coming back. I think it's fair to say you're assuming lossless transmission lines.

> >>When a wave is destroyed, it MUST, of necessity,

Fact is I'm not much good at guessing. Annihilation is the only example I can think of where something is actually destroyed and gives up all it's energy. Perhaps you could let me know what other real examples I'm overlooking. Thanks for the spell check by the way.

Bill -

Follow the assembly instructions and you should be able to adjust the Ringo
for the
dip at your desired frequency. Check that you have GOOD coax (the problem
that you describe could
be a coax problem and not the Ringo.
Many blame the antenna when it real problem is marginal coax --- passable
at HF frequencies --
but totally unacceptable at VHF.

The Ringo ranger II is based on the original W1BX Ringo design. The Ringo
Ranger II is the current and latest design featuring three 5/8 wave
radiating elements and an adjustable 1/8 wave phasing stub. This results in
a very low angle of radiation over your desired coverage area.

Dear Joe S. (unknown call):
Here is the "word" on your antenna.
In the 50s and early 60s the antenna was known as a TC-88B. Latter in the 60s it was renamed as the TB4EC.
It is said to weight 30 pounds and have an 8 foot boom. It fits your description exactly with the 20 meter reflector having a "hairpin resonator." The black box is to connect to the front, driven element as a balun.
In other words, the black box goes across the driven element, but the "loop" goes across the 20 m reflector.

All of this came to light when I was looking for information about my old TB6EM. I may, at last, have found a good home for it.

They aren't too bad. The "II" has a decoupling section, so feedline
radiation is fairly low. The original ringo ranger had no decoupling
though, and it was more prone to problems. He can get the manual in
PDF format at their website. It will tell the exact dimensions for a
given center freq you choose. MK

Actually, the loop could probably be a bit smaller than that and still
work ok.
If you had a 22 inch loop, it would be tapped at the midpoint , or
even less maybe. A 15 inch loop could probably work. It would just be
tapped to use more of the coil. I was thinking a 10m loop was 11
inches. Actually, I think it's closer to 9-10 inches dia, so 18 inches
would be about the "standard" size for a 20m antenna. MK

> dissipative load.

How does the wave about to be dissipated differ from the wave that is
about to be canceled? Hint: they are identical.

How does the wave know ahead of time whether it is going to encounter a
dissipative load or not? It obviously cannot know ahead of time so all
waves with the same V and I in phase carry the same amount of energy.

A wave about to encounter a dissipative load or the same wave about to be
canceled carry the same amount of energy. The wave gives up that energy in
both cases. In the first case it gives up its energy as heat. In the second
case, it gives its energy to the constructive interference.

Ahhh, but the Melles-Griot web page specifically states that the enhanced intensity comes from the *REFLECTED* canceled wavefronts which were obviously rearward-traveling waves before the cancellation. Sorry, you lose again.

> lecturing to us about. It's quite apparent there is no such route.

It is quite apparent from reading the Melles-Griot web page that there
is such a route. Please reference the drawing under "thin-film interference"
on the Melles-Griot web page.

```
| 1/4WL |
Laser-----air-----|---thin-film---|---glass---...
| |
F B
```

During steady-state, there is a reflection from plane B that travels
rearward toward plane F. The reflection from plane B has an associated
power flow vector. What happens to that rearward-traveling power flow
vector to reverse its direction at plane F? That power flow vector is
represented by a green line on the drawing under "thin-film interference"
on the Melles-Griot web page.

Nope, I certainly don't lack the intelligence to recognize the difference.

>>You continue to confuse normal
>>interference patterns with wave cancellation.
>
> If that was true then your Melles-Griot crutch would go out the window.

You still just don't get it. When a wave ceases to exist, that event
is nothing like normal interference. When a wave ceases to exist, it
must give up its energy at the point where it ceases to exist.

It is obvious what happens, Jim. It is just not obvious why it happens.

> Is it that you
> wonder why the transmitted intensity goes up by a factor of four when
> two equal amplitude waves constructively interfere?

Hecht, in _Optics_, says it is because of destructive interference. I
agree with Hecht. The destructive interference energy comes from the
destructive cancellation of two rearward-traveling reflected waves.
Where do you think the constructive interference energy comes from?

> There is no energy being conveyed by the cancelled waves, so no energy
> is "destroyed" when the waves are cancelled.

Of course, that is nonsense. Waves with the same V and I in phase are
just alike, energy and all.

> Well, it seems they don't propagate beyond the cancellation point. They
> convey energy no further than the cancellation point. But I don't see
> need of worrying that energy might be destroyed at the cancellation
> point. I think we pretty much agree that doesn't happen.

The point is that those waves convey energy to the cancellation point and then
they are destroyed. Energy cannot be destroyed. It doesn't flow toward the
source. ERGO, it must flow toward the load and it does as constructive
interference.

>>Where does the energy in the destroyed waves go?
>
> It doesn't go. It went elsewhere instead.

Bafflegab. If "it went elsewhere instead" then it did go somewhere. It
migrated from the destructive interference event to the constructive
interference event exactly as Hecht says.

> I've asked that you use quotes when you refer to things I've said.

Don't need to. the '>' marks show exactly what you said for all to see.
You uttered the same nonsense above. Tell me, Jim, are the following
waves conveying energy or not? If you can't tell, how the heck is the

wave smart enough to know whether to convey energy or not?

---------150 ohm feedline------------50 ohm load
forward power = 133.33W
reflected power = 33.33W

> by the cancelled light waves.

Bafflegab again. Waves cannot exist without energy. If waves possess energy, then that energy must be conserved after destruction of the rearward-traveling waves. Waves don't go anywhere after they are destroyed. Energy cannot be destroyed. Where does the energy in the destroyed waves go? It cannot stand still and it doesn't flow toward the source. We already know it flows in the forward direction as constructive interference. We know the destroyed waves were rearward-traveling waves. The rational conclusions are obvious.

If you want to paint your 'J'-pole it shouldn't be a problem
at all. The copper oxide does not contribute any 'gain' to any
antenna. But then again, it doesn't hurt anything either.

My personal choice would be RG-213. If you feel the need for a balun,
I would use the type that becomes the center conductor for the dipole.
Then you just screw the coax on the bottom. I rarely use a balun.

Even if you are not an ARRL member and/or disagree with its policy, you should seriously consider contributing to this fund. If the BPL technology ever gets implemented, this may very well be the end of ham radio as we know it. Make no mistake about it - we're talking 60 dB noise increase across the entire HF, not dropping the Morse requirement! And for what? So that people in the rural areas of USA can have a faster download from porn sites?

https://www.arrl.org/forms/development/donations/bpl/

A measly $25 - $100 can help prevent your $5000 equipment from becoming an expensive coffee cup warmer.

Joel,

Obtain some ordinary, twin, clear-plastic insulated, aprox 0.8 to 1mm diameter, flexible, stranded, speaker cable, sometimes known as zip-cord. Like Radio speaker-cable Shack stuff.

It has an impedance in the range 120-140 ohms. I once measured some. It tends to be independent of wire diameter. For balun applications it is non-critical anyway.

If its an HF choke-balun just wind 8 or 10 uniformly-spaced turns on a 38mm or 50mm ferrite ring, HF-quality, permeabilty between 200 and 400. It will handle a few 100 watts. The whole thing is non-critical.

Guidelines - Inductive reactance of the winding at lowest operating frequency should not be less than 4 or 5 times the lower terminating impedance. The length of the cable should not exceed 1/12th or 1/9th of a wavelength at the highest frequency of use, taking into account the propagation velocity of the cable itself. VF of the cable is roughly 0.75 to 0.85

Just wind some twin cable on a core. If it works don't bother fixing it.

For a fixed 4:1 impedance transformer ratio, say 50 to 200 ohms, just connect the two wires in the cable in series with each other.

You may find program BALUN4 interesting.

I'll ignore the "falsely claimed to have worked" allegation, but you can check my DXCC Challenge stats with ARRL if you like: http://www.arrl.org/awards/dxcc/listings/challenge.html#challenge ;they're backed up by verified QSLs.You can stop by and inspect the cards yourself, if you don't trust the DXCC desk.

Unless you built your station from a few piles of unrefined sand, coal, and iron ore, you've simply chosen a different level of technology and automation. That's your choice, and that's fine, but you're in no position to play "holier than thou". Given the ground you've staked out, I am wondering what you're doing using a computer to communicate with other amateurs. Shouldn't we be having this conversation with straight keys and spark equipment on the low end of 20m?

For the record, DXLab applications automate the mundane aspects of DXing, which means you can spend more time operating and less time paging through paper logs or filling out QSL cards or sorting through DXing tip sheets looking for operating patterns, or blindly seeking secondary propagation paths. One dimension of amateur radio has always been "do the best you can with the technology available". The technology that DXLab exploits is called modern software engineering - the ability to rapidly produce high-quality applications responsive to the needs of their user community. Unless you wrote all of the software on that PC of yours, you're probably using some of this technology too!

Couldn't of put it better myself.

Giving Brian the benefit of the doubt would at best put him into category 4,
the RAs motive is clearly category 5, The RSGB category 2 and 3,
and each group, possibly inadvertently, supports the other

and all the result of Not having a Docket system.

792. Will this work?

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-09 06:50:25 UTC
From: Batman <kg0wx@yahoo.com>
Message-ID: <RWOOa.528829$3n5.477400@news2.central.cox.net>
Source record: 113036

I'm moving to a new QTH in 4 weeks. I'd like to put up the
following antenna:

130' inverted V fed with Radio Shack 300 ohm twinlead
fed by a LDG 4:1 balun fed by a LDG Z-11 autotuner.

The rig is a Yaesu FT-817 (5 watts max output)

I was planning on getting a Van Gordon "All bander"
antenna, a 130 foot dipole fed with 450 ohm ladder
line to the same balun and tuner.

I now want to build my own using Archer rotor cable
for the elements (18 ga.) and 300 ohm twinlead for
the transmission line. I do not know how long a line
I will need.

What I'm concerned about is the VSWR and RF handeling
capacity of the RS heavy duty 300 ohm line.......

Opinions?

Since the RSGB has already destroyed ham radio in the UK - it's little more
than multi-band CB now - we feel there is little to be lost that hasn't
already
been sabotaged by our supposedly "National Radio Society".

So, roll-on BPL in this country - the sooner the better. The king is
dead...etc.

I hope you get mega-flamed for that last sentence. What a disgraceful
comment ! And what an appalling slur on the folks who live in rural
USA..... !!

Most of the FCC senior officials are lawyers who don't have a clue
about the technical side of radio. They wouldn't know a door knob
from a transistor. Come to think of it, a know lot of hams that
don't either.

I am using an antenna based on the NorCal
"Crappie" dipole with my FT817. Theirs is 44'
across the top, mine is 66'. I have heard that
the 44' was carefully chosen for "best" all band
(80 -> 10) coverage. I am happy with mine, and
have been. The "permanent" antenna is fed with
450 ohm ladder line. The temper antenna is fed by
41' of #22 zip cord. Magic length determined by
being what was left over after cutting 25' off one
end of 100' roll of speaker wire, after split 33'
of the other end to become the flat-top portion.
Both antennas work great and I have no plans to
"improve" them any further.

Sure, I'm using sky wave. But the average mobile antenna, being a
vertical, is not really designed with NVIS in mind. I never expect a
truly good NVIS signal from a mobile antenna on 80m compared to a
dipole or whatever. I don't try to improve the horizontal componant.
But I do try to improve the efficiency. And that will improve the
signal in all directions equally. As far as I'm concerned, a low angle
ground wave test, is about as good as the high angle sky wave test, as
far as telling which antenna , or antenna system is the best, if the
antennas are shorter than a 1/4 wave. Actually, I would prefer the
ground wave. It's more stable, and easier to note small differences.
You haven't changed my mind on this part. What math should I do?

I think *most* people have enough sense not to place all the blame or
glory on any one part. All my personal testing has been done on the
same mount, so the antenna is the difference in my cases.
>

I did? When? I've never been in a "shootout" yet, except in my
driveway.

So if a relatively poorer antenna on a
> good, well prepared automobile (or a Suburban with a 20 foot flatbed trailer
> with several 1" braids supplementing the trailer hitch) produces higher
> measured field strength than a better antenna on a poorer mounting choice,
> like a tiny car for an extreme example, then the poorer antenna is better?

If you say so...That question is a bit silly for me to answer.

> That's what your "shootout" will show. Shootouts are good ego boosters, but
> show relatively little about individual antennas.

Sure they are, but I don't need to know about the individual antennas.
They are easily calculated and/or modeled. They are pretty much
"pre-known" to a fairly accurate degree before you even start. I knew
almost exactly what my last antenna I designed would do in efficiency
per a given ground loss number, before I even built it.

I didn't say antenna
> systems, I said antennas, which is what the original inquiry was about.
> Now, if he had asked about improving the platform and system, then that's
> additional material. Start with the biggest, lowest vehicle you can find,
> add copper straps,.....

I believe I only mentioned antennas in my first post to him. And I
still stand behind my rankings of them. They have all been tested on
the same mount at various times.
I remember Cecil discussing one such case. I've never said the
"shootouts" are ultra accurate or anything. But I do think they are
good enough for "gov" work. To me, it's just something to do, and
compare and maybe share ideas on mobile installations. No one is
twisting your arm to go, if you don't like they way they measure
things. MK

Yes, but with a good bit more feedline loss than the ladder line only
fed dipole on some bands. Myself, I hate G5RV's. Not because of the
dipole length, I don't like the mixing of feedline types. I find a
tuner/coax/choke-balun/ladder line feedline/mess quite goofy. That
means I also hate many windoms fed in the same way. But actually, I
hate most all non balanced antennas. I'm picky, and think I deserve
only the best...
No grey area in my thinking...:/ I gotta side with Reg on this one..

These are excellent antennae. I bought one a couple of months ago. I hear repeaters up to 180 miles away no problem - all the time, and most days I can hear the Caen repeater in France and I can activate it with 25W. That's a 230 mile trip. If you like, I can scan and e-mail you the measurements to set your antenna to.

Cecil, W5DXP wrote:
"50V at zero deg. and 1A at 180 deg. = 50W
50V at 180 deg. and 1A at 0 deg. = 50W"

Cecil`s first 50W can be a reflection from a too-high load which reverses phase of current but not volts.

Cecil`s second 50W can be a reflection from a too-low load which reverses phase of voltage but not amps.

You can`t get Cecil`s second 50W by reflection of the first because reflection only reverses volts or amps, not both.

You can get Cecil`s second 50W by an additional 180-degrees of phase rotation, i.e., phase inversion for both volts and amps. This does not happen at a reflection. A reflection only inverts volts or amps, not both.

Cecil`s imaginary volts and amps are hard for me to put together. A load is either too high or too low. It can`t be both. The reflection is possibly Cecil`s first or second 50W, not both.

Re-reflection makes a single forward in-phase wave, combining new energy with the re-reflected. It can not make Cecil`s second 50W from his first 50W.

I`m eager to learn.

Best regards, Richard Harrison, KB5WZI

We are talking about transmitting conditions, not receiving conditions.
What is a "shorted receiver"? What causes the short?

200W source--50 ohm feedline--+--1/2WL 150 ohm feedline--50 ohm load

> Cecil`s first 50W can be a reflection from a too-high load which
> reverses phase of current but not volts.

Correct: It is a reflection from the physical 50 ohm to 150 ohm
impedance discontinuity. It is 25% of the source power where
|rho|^2=0.25

> Cecil`s second 50W can be a reflection from a too-low load which
> reverses phase of voltage but not amps.

Correct: It is 75% of the reflection from a 50 ohm load fed by a
150 ohm feedline where (1-|rho|^2)=0.75. The reflected power on
the 150 ohm feedline is 66.67W.

> You can`t get Cecil`s second 50W by reflection of the first because
> reflection only reverses volts or amps, not both.

Correct: These are two *separate* reflections, one from a 50 ohm to
150 ohm impedance discontinuity and the other from the 50 ohm load
fed by 150 ohm feedline.

> You can get Cecil`s second 50W by an additional 180-degrees of phase
> rotation, i.e., phase inversion for both volts and amps. This does not
> happen at a reflection. A reflection only inverts volts or amps, not
> both.

The 1/2WL of feedline causes a 180-degree phase rotation.

> Cecil`s imaginary volts and amps are hard for me to put together. A load
> is either too high or too low. It can`t be both. The reflection is
> possibly Cecil`s first or second 50W, not both.

One reflection is from the 50 ohm to 150 ohm transition in the feedline.
The other reflection is from the 50 ohm load.

> Re-reflection makes a single forward in-phase wave, combining new energy
> with the re-reflected. It can not make Cecil`s second 50W from his first

Have you got any approximate dates for these cases so I can see if they are
real?

As regards Messrs M & R, maybe a little professional 'nod' is called for.

There was a case near here not so long back. A secretary took some headed
note paper home (quite legitmately to do some extra typing for the firm) but
her partner used some to fake a letter to intimidate a trademan. Secretary
lost her job and that was just the start of it.

Hi Ron:

The ground rods are good for lighting protection but not much good for a RF ground. You need a better RF ground. I would also put some ground radial wires out from as close to the tuner as I could get them. At least 1 for each band I wanted to operate on. In grounding there is almost no such thing as too much ground. That said hooking up to the ground rods as you said will work but with ground radials it will work much better. The problem with random wires and verticals is their both like ducks. The both look neat and simple from the surface but there a lot going on below the water line.

From: John Passaneau <jxp16@psu.edu>
Message-ID: <beh7vb$113m$1@f04n12.cac.psu.edu>
Source record: 113058

Hi Jeff:

Yes it will lower the impedance but only because the of the lower loss in the larger diameter. Remember RF current flows only on a thin skin layer on the surface of the conductor and the higher the frequency the shallower the skin depth is. Making the conductor bigger in diameter lowers the RF resistance of the conductor and the RF resistance of the conductor is in series with the radiation resistance of the antenna. Also as the conductor diameter increases it will need to become shorter to maintain resonance on a give frequency.

The only information I have is from posts that have appeared on this NG, mainly from 'Airy R Bean'. I assume these cases were heard in the Chippenham area, but I know nothing further.
If I received a letter from a Solicitor acting on someone else's behalf, I would reply to the Solicitor, and not his client. If the letter then proved to be a forgery I'm sure this would be regarded as a very serious matter.
I'm sure in the case you mention the secretary losing her job was the least of their problems!

"What is a shorted receiver?"

A transmission line has a sending end and a receiving end. Many authors, and I am not an author, call the load at the receiving end of the line simply "the receiver", just like the listening device on the end of a telephone line.

The short is caused by a "small" length of conductor connecting the two-conductor assembly comprising a transmission line. The result is zero impedance at the short-circuit point on the line.

Best regards, Richard Harrison, KB5WZI

> coincide?

Did you see the diagram? The two signals are s11*a1 and s12*a2
in the s-parameter equation b1 = s11*a1 + s12*a2

That's essentially the same equation as

Vref1 = Vfwd1(rho-v) + Vref2(tau-v)

Vfwd1(rho-v) = 50V at zero degrees. Vref2(tau-v) = 50V at 180 degrees.

Iref1 = Ifwd1(rho-i) + Iref2(tau-i)

Ifwd1(rho-i) = 1A at 180 degrees. Iref(tau-i) = 1A at zero degrees.

Of course, the appropriate 'rho' (reflection coefficient) and 'tau'
(transmission coefficient) must be chosen. They are not the same
values for voltage and current.

The point is, those two waves superpose to a voltage of zero and
a current of zero. What happens to the energy that pre-existed in
those waves before they are destroyed?

Because he has been sending letters purporting to come
from them without due authority. The letter at the URL
you gave is clearly not from a qualified legal professional
but from a deluded fantasist who fancies he is Perry Mason.

Threatening behaviour looks favourite, but I'm sure Messrs
Morgan Raynor can come up with something much nastier to
charge him with. Forgery, deception etc. etc. I suppose he
doesn't want their attention drawn to his activities.

Not at all. Absolute truth. You can either try to understand what's going on, or you can continue to blither on with your ignorant misconceptions as you have below. It's your problem, not mine.

Here's a hint for you Cecil: you seem to have forgotten that where there's destructive interference, there's always constructive interference - even if the light is coming from Alpha Centauri. It's that conservation of energy thing I mentioned.

>
> Anyone seen such a test ?

Here it is in a nutshell for 75m. Bugcatchers with large top hats and
screwdrivers with large top hats are close to equal at the top of the heap.

Taking away the top hat costs about 2 dB. ~30-40% loss of power

Hustler and Outbacker are about 9 dB down from the top. ~85% loss

Hamstick is about 12 dB down from the top. ~95% loss

11.5' whip is about 13 dB down from the top. A 102" whip
would be even worse.

Assuming the antenna is "the receiver" during transmit conditions,
the antenna is not shorted. So what is the purpose of the short
at the antenna? I must be missing the point.

So as I was saying, Cecil is in a battle for newsgroup points (maybe his ISP is offering a premium). He is primarily concerned with winning. To do so his opponent must lose, of course. The truth is virtually irrelevant to him. The fact that he can produce no physical or mathematical support for his assertions is irrelevant to him in this endeavor. His only hope is a particular interpretation of some prose on a web page. But he must also ignore the facts that support the correct interpretation of the web page. He comoflages this by producing blizzards of insulting posts in hopes that his correspondent might be badgered into submitting to his version of nature - or at least, leaving the discussion so that his aberrant vision can be promulgated unopposed. The longer the process takes, the more insulting and ridiculous his writing becomes.

Ahhhh Jim, that has been the cornerstone of my argument all alone.
I see that my multiple quotes from _Optics_ by Hecht have finally
sunk in on you. We know that, in a Z0-matched system, constructive
interference takes place on the load side of the impedance discontinuity.

That means that destructive interference must be taking place on the
source side of the impedance discontinuity. Nothing exists there
that can interfere except TWO REARWARD-TRAVELING REFLECTED WAVES!

The light coming from Alpha Centauri contained energy when it was
generated and contained energy when it reached the earth. It
contained energy when it was forced to interfere here on earth.
Your following assertion is ridiculous in the extreme.

> It (Alpha Centauri) made the decision not to send energy at the
> same time it decided to send the two beams to us out of phase.

Face it, Jim, all EM waves contain energy. Your energyless wave
theories just won't fly. If the energy is zero, the E-field is
zero, the H-field is zero, the voltage is zero, and the current
is zero. Aren't you ashamed to call such a conceptual abortion
a "wave"?

So are you finally ready to admit that the reflected energy power
flow vector does indeed represent energy in motion?

I am going to conceed part of the argument to you, Jim. I simply cannot
match your diversions and ad hominem attacks. I hope what you were after
is the *King Ad Hominem Attack Crown* because you own it, hands down.

When you have nothing technical to offer and are being defeated in the
technical argument, you resort to the above. Replace "Cecil" with "Jim"
and you are describing yourself perfectly. Such attacks are why I broke
off email communications with you. You simply cannot stand to be proven
wrong in private or in public.

Anytime you want to discuss technical topics, please do so. Otherwise,
I am just not going to respond to your ad hominem garbage. You win
that war, hands down. I surrender.

> the of the lower loss in the larger diameter.
==========

John, must add something more.

The antenna behaves as a single-wire transmission line. Its feedpoint impedance decreases with increasing conductor diameter because of the increase in capacitance and a decrease in inductance per unit length.

The reduction in conductor loss resistance has a lesser effect than L and C, especially with big conductor diameters as when self-supporting aluminium tubes are used.

Forget the balun and just feed the dipole with rg-8 or beter coax.
You will loose more in the balun than you will gain in any other way.

You can calculate the losses in the line to a dipole Dipole3.exe. I have
not yet tried the Inverted Vee program.
http://www.btinternet.com/~g4fgq.regp/
In my application is was not significantly different from using bigger,
heavier, more expensive 450 ohm line.

Ken,
The 300 ohm line should be able to handle anything
you'll be able to put into it with a FT-817 with no
trouble at all. The only worry I would have is how
long the mechanical connection between the antenna and
the twin lead will last. 18ga wire isn't very durable
when it's moving around in the wind...

whitehat,
If there is nothing bridging the 1" gap at the end
insulators, the last 22' of wire are not part of the
antenna (or part of it's missing). So, that would make
it a 30 meter dipole (close). Personally, I'd get rid
of the 'extra' 22 feet on each end and replace it with
a non-conducting cord/rope of some kind, if you're going
to use it as a 30 meter dipole.

You could if you cut down on the number of them by a factor of two or so.

How many times do you think the word 'you' should appear in a technical discussion? Count how many times that word appears in your posts, and compare it with the number of times it appears in my posts.

Ok, you don't need large coax because of power -- loss is the only consideration. 25 meters of RG-58 coax will have about 5 dB loss; RG-213 or RG-8 type cable, a bit under 3 dB. Good quality foam dielectric RG-8 size cable has a bit under 2 dB loss (because of its larger center conductor, not because of lower dielectric loss). Other cable types have less loss yet, but are generally more expensive.

It's up to you to decide how much you're willing to sacrifice in weight and cost to get reduced loss.

A balun can be useful for a number of different antenna types at 2 meters, including a ground plane and J pole. When the feedline drops directly down from these antennas, considerable current can be induced on the outside of the feedline by mutual coupling. When this happens, pattern distortion can result. Modeling shows that the gain at the horizon can be reduced by up to 2 dB or so as a result, depending on the feedline length. This is about the difference between using RG-58 and RG-8 sized cable as feedline.

I don't have any direct experience with 2 meter baluns, but I'd guess that about 10 decent sized cores of type 43 ferrite slipped over the outside of the coax would suffice. Or you can wind the coax into about 4 or 5 turns on a large core of the same type. An effective balun can be made by just winding a few turns of coax into a loop, but I don't have dimensions for 2 meters. To be effective when using a ground plane, J pole, or similar antenna, you'll need two baluns -- one at the feedpoint, and another about 1/4 wavelength below it.

Someone said...

"I also have heard that removing the oxide layer by scratching the surface whilst under an oil film then soldering with ordinary solder works OK."

This works, I've demonstrated it many times to bewildered unbelievers.

Put a small puddle of oil on the aluminum. Use you pocket knive to scrape the aluminum under the puddle of oil. Thus the oil keeps the aluminum from instantly oxidising, Use a BIG HOT soldering iron and plunge the solder and the iron tip in the puddle of oil making contact with the aluminum. When the solder and the aluminum are hot enough the solder will flow and "tin" the aluminum.

Then solder a lug to the bunch of solder which is soldered to aluminun.

You'll think you have witnessed a miracle.

Remember: BIG & HOT!

Cecil, W5DXP wrote:
"What is the purpose of the short at the antenna?"

I can think of several possibilities, reaonate the antenna, broaden the bandwidth, and suppress lightning, if the short is at the end of the right stub and properly grounded. But I doubt that is responsive to your question.

I`ve forgotten how or why or which short we were discussing. I`ll speculate it was an illustration to simplify explanation of transmission line behavior. Shorts make manifest line action more readily to some observers than do too-low Z`s.

Then, there is the junction which has been called a "virtual short" because it allows no reflected energy reach back to its source but re-reflects all the reflected energy toward the load.

The junction is reflective because it is an impedance bump.

The junction is impermeable from the load side because the transmitter side is never at lower strength than the load side.

Best regards, Richard Harrison, KB5WZI

I count 15 references to me and zero technical content. How many times should
a reference to your opponent appear in a technical discussion? By your own
example above of your preferred way to post, I guess your answer must be 15 times.
Whatever it is, you outdid me by a magnitude. Congratulations, you win the all time
ad hominem attack award plus the award for the ratio of most personal references
to your opponent to the technical content of the posting. It's a record
that may be someday be equaled but never bested. It's hard to beat a ratio
of infinity.

the green line is not for a perpendicular reflection hence there is no
interference and no cancellation so this example can not be compared with
coax.

the slightly more appropriate discussion in the case of normal incidence
below that leaves out the important points about where the cancellation
occurs... which as you yourself has said is at the mismatch points, which in
the thin film case is at each of the interfaces to the film, not within the
film, and not in either of the other materials, but just at the film
surfaces where the actual reflections and refractions take place... I
propose we dub these interfering 'waves' as 'virtual waves' since they never
leave the cancellation point, they are a way of accounting for the various
components that the reflection and refraction coefficient say should be
there but are actually canceled before you can see them.... somehow the
'virtual' label just seems to fit.

the 'missing' mechanism is the specification of the boundary conditions at the mismatch point. that is where all the cancellation occurs as you have acknowledged Cecil. there is no reversal, you just solve for the voltage or current at the mismatch point, apply that as the boundary condition to the wave equation in each direction and it all adds up.

60db is a very high figure. Where does this figure come from.
If this is correct wouldn't the VOA,BBC and others nations
broadcasts be shut out from America? Something is odd here,
I can't believe that the FCC would intentionally jam all HF
frequencies from citizen useage.
If the 60db figure is an exageration to get funds then the
augument is lost before it starts !
Even if it is correct Ham Radio could not do anything about
it because its members have shown little interest in
perpetuating the hobby with actual deeds.

Steven Best says that total re-reflection is a fallacy. Do
you disagree with Dr. Best?

> The junction is reflective because it is an impedance bump.

But the impedance bump doesn't have a reflection coefficient
of 1.0 so how can it possibly re-reflect 100% of the reflected
power? This is the question I have about Walter Maxwell's
"virtual short". Wave cancellation along with normal re-reflection
explains everything perfectly.

Good grief, David, just as the flow chart cannot be drawn upon a point,
the reflection chart cannot be drawn in one dimension. Assume for purposes
of illustration that the reflection *IS* perpendicular.

Of course it adds up, David. If my bank account is the same at the beginning
of the month as at the end of the month, you would argue that it adds up
and we can assume there were no transactions during the month. I am not interested
in being seduced by the steady-state religion and everything simply adding up. I
am interested in the underlying transactions. Since the behavior of matter is
already known on the macroscopic scale, why do you suppose we spend billions
of dollars to find out what is happening on a microscopic scale? Aren't
you the least bit curious at to what is happening underneath the steady-state
simplified model?

Art Unwin KB9MZ <aunwin@insightbb.com> wrote:

>60db is a very high figure. Where does this figure come from.

Visit www.arrl.org, take a look at their hot-news article on BPL near the top of the page, follow the link to the full story, and then look for the link which lets you download the ARRL's 121-page response to the FCC inquiry directly from the FCC's web site.

The ARRL response contains a bunch of the studies that the ARRL did. Some of them are based on standard sorts of theoretical calculations (e.g. NEC2 modelling of power lines as antennas, combined with data on the probable spectral density of BPL signals, with power levels assumed to be at or near the FCC's current Part 15 emissions limits).

If I recall correctly, the response also cites a number of studies of BPL systems which have been performed overseas. These studies showed that serious problems do exist.

>If this is correct wouldn't the VOA,BBC and others nations
>broadcasts be shut out from America?

It seems likely.

> Something is odd here,
>I can't believe that the FCC would intentionally jam all HF
>frequencies from citizen useage.

When money is involved, government bodies have been known to do some very strange things.

It has also become apparent that some very senior FCC officials are woefully ignorant about radio. Political appointees, I suppose.

>If the 60db figure is an exageration to get funds then the
>augument is lost before it starts !

So, go read the studies and decide for yourself. The ARRL has had citations for the overseas studies, and preliminary versions of their own sets of calculations, on-line on their Web site for many weeks.

The ARRL pages point out that previous studies in Japan had led the Japanese government to a similar set of conclusions about the interference potential, and that the Japanese government has concluded that BPL technologies of the sort being discussed _cannot_ be put into

production in Japan because of this unacceptable interference potential.

>Even if it is correct Ham Radio could not do anything about
>it because its members have shown little interest in
>perpetuating the hobby with actual deeds.

Feh. Looks to me as if well over 1000 individual Ham operators took the time to write down their responses to the FCC's NOI and post them on the FCC web site (this isn't counting the numerous duplicate uploads, which I suspect occurred because the FCC's upload server appears to be running on a Commodore 64-grade system and had a nasty tendency to hang during the upload/confirm process).

I spent 3-4 hours crafting my own comments on Saturday, and uploaded them successfully on Monday morning.

geez.... you just don't get it do you. the COMPLETE answer is in the wave equations solved for the boundry conditions at the mismatch point. there can be nothing else, all voltages, currents, fields and waves are accounted for AT THAT POINT! And you have already agreed to that! it has nothing to do with the steady state solution! why do you think i set up that specific case that you glossed over? if you had taken the time to go through each step of it the solution would have been obvious. ALL INTERFERENCE, WAVE REVERSALS, CANCELLATION, WHATEVER YOU WANT TO CALL IT OCCURS AT A SINGLE POINT!

ok, i'm done trying to beat it through your head.... as they say elsewhere.... plonk!

I see the drawing. It's similar to the one in Born and Wolf. Only the
one in Born and Wolf has detailed mathematical descriptions that
accompany the drawing. But I don't find any of the rest of what you say
on the web site (or anywhere else). Sorry OM.

> a lossless line?

No. But I would call it something other than a good example of wave cancellation. If 33.33 watts isn't at both ends of the 150 ohm transmission line, then your rho at the second interface is unequal to the rho at the first interface, and you don't have an impedance match point and power would be reflected by the match point.

==========
Hi Frank,

As nobody, in an unknown environment, knows what is the impedance of a windom within plus or minus 25 percent, in the midst of such uncertainty any differences due to making it a sloper will be lost in the fog. It can only be measured.

The sloping performance, in some respects, may actually be an improvement. But, of course, neither you nor anybody else will ever know.

It is suggested you go ahead with the sloping version. You will at least be able to confirm that it works satisfactorily. But you will not be able demonstrate that it works OK due to it being a sloper, or even because it closely resembles a windom.

You could obtain some interesting results. Other experimenters unable to erect high horizontal antennas would like to hear.

There are two versions of a windom. The first original version, which goes back many years, has a single-wire feedline offset from the dipole centre. This is modelled in program WINDOM2. Both versions have intentional radiation from the feedline which is an integral part of the antenna. A tuner is essential for both versions when used for multi-band operation.

Uhhh, this one is even better than Christian Science. What about all the government, military, ship to shore, and navigational use of the HF spectrum? Do you think that the FCC is actually going to allow malicious interference to disrupt these services?

Whether the ARRL is involved or not, and if the statement concerning noise is true, it will never happen.

Save your BPL money and take your girl friend out for a Prime Rib dinner and a night on the town......You'll get a hell of a lot more bang for your buck.

I doubt that any quantum physicist would agree, David. The wave equations are a tool for solving problems. They don't necessarily bear any resemblance to reality as any quantum physicist will tell you. They certainly don't dictate to reality as you appear to think. I am studying the physics underlying the steady-state model. I apologize if my quest for knowledge threatens your sacred cow.

What does your "COMPLETE" steady-state model say about where the constructive interference energy comes from at a Z0-match point? What does your "COMPLETE" steady-state model say about what happens to the energy when two waves are destroyed by destructive interference during the elimination of reflections?

> ALL INTERFERENCE, WAVE
> REVERSALS, CANCELLATION, WHATEVER YOU WANT TO CALL IT OCCURS AT A SINGLE

What would you consider appropriate coax for VHF? The run is c. 30
feet, though I'm using a 50 foot cable (RG8, UHF couplers). Antenna
is Optek 2m/70cm vertical, and currently performs worse than the
rubber duckie for my VX-5R.

Yes it was. So what happens to the reflected power Poynting Vector
(that the above reference says exists) when it encounters the
impedance discontinuity?

100W source--50 ohm feedline--+--1/2WL 150 ohm feedline--50 ohm load

The reflected power Poynting vector on the left side of the impedance
discontinuity is zero. The reflected power Poynting vector on the right
side of the impedance discontinuity is 33.33W pointing toward the left.
For about the tenth time, what happens to that reflected power Poynting
vector?

I have told you time after time, that the load impedance doesn't matter
and the feedline length doesn's matter. The losses in the feedline
don't matter. All that matters are the conditions at the match point.
Nothing else matters.

>> 50V at zero degrees and 1A at 180 degrees = 50W

Dodging another technical question, I see, and we all know why.
You know that the sum of the two above waves is zero volts and
zero amps, i.e. destruction of the two waves in their direction
of travel. Where does the energy go when the waves go to V=0 and
I=0 in their direction of travel. That's question number 73 that
you have refused to answer.

It seems that everything you don't know the answer to is a
non-sequitur. I fully understand your attitude.

Gosh Cecil.
That's pretty much what I've seen with a little field strength meter on the hood over the last 40 years of mobiling..
And certainly the biggest, center loaded, resonant, matched antennas are vastly better than a non-resonant whip and a tuner.
All this second-guessing about shootouts will never cause a tuner-and-a-whip to beat a 13 foot resonant monster.
Personally I think competition makes folks think about their radio installations.
That's a good thing.

Its the new ARRL policy. In the past they tried to get you to give them your money based on shear blind loyalty. Now'a'days they want to scare you into giving them the bucks. Its the old "If you cant coax them, scare the crap out of them" fundraising policy. The Catholic Church has used this for years and years.

Just think, when this Echo-link nonsense takes over (ala the ARRL's and their "Hinternet"), we'll all have $2000 CB radios.....I know I cant wait!

For 50 feet of coax almost any of the coax that is the size of rg-8 should
be ok. You could spend a little more and get some of the 9913 type or
lmr-400.
Even the rg-8x might not be too bad for 50 feet for vhf.

RG-8/U is a generic designation these days - and I rarely believe the specs
on any cable
listed with this designation.
During the CB craze in the 1970s, we set up a bench measurement
for 100 foot rolls of RG-8/U coax (e.g. Columbia, Alpha, Belden, no name,
foamX)
Finding quality and consistency were problematic.

The most important characteristics that I look for are:

Known manufacturer (consistent quality & specs)
Known spec or model number (e.g. Belden number)
Good shield coverage
For VHF -- less than 1.7 db attenuation / 100 feet at 150 MHz
Correctly installed PL-259 (when using the UHF connectors) or N connector
(preferred)

9913 and LMR-400 provide a small improvement for 50 feet of coax - 0.5 db
max

That sure sounds as if something is amiss. Full-size RG8 cable ought to have tolerably low losses on 2 meters, and even on 70 cm, for that sort of a length. It'd be better to cut it down to length, of course, but I wouldn't think that it'd be _that_ bad even on 70!

First thing I'd suggest, is do a trial installation of a different antenna at the end of that coax, and see if the signal gets any better. If it does, then your antenna has problems. If not, then the coax is bad.

One definite problem with PL-259 connectors is that they are by no means waterproof-by-design. If you've had that antenna up through one or more significant rainstorms, and if you didn't install extra waterproofing (e.g. Coax Seal, silicone sealant, etc.) over the whole connector area, then you may have water infiltration into your coax... the braid can easily "wick up" moisture, and you can end up with water-soaked insulation and with water running down all the way into your shack. I tend to prefer N connectors for this reason among others.

I've got a homemade Copper Cactus two-arm J-pole, at the end of about 30' of RG-8 (the full-size, not the "RG-8 mini" aka RG-8X) and both bands work very well indeed. In fact, it's almost unusable with my VX-5 because the strong signals overdrive the VX-5 RF section and I end up with a lot of intermod from local paging transmitters.

Cecil,
W5DXP wrote:
"Steven Best says that total re-reflection is a fallacy. Do you disagree with Dr. Best?"

I`ll play along. On this issue, Dr. Best may be mistaken. Individual testimonies may not be very reliable, but large numbers become a preponderence of evidence. Numbers of operators claim to be able to reach near 1:1 SWR at their transmitter outputs while having greater SWR`s in other parts of their transmission systems. I believe them. It agrees with my own experience. The 1:1 SWR at the transmitter means reflections were stopped short of their return to the transmitter. Re-reflection at the match point is therefore very near total.

I have similar practical experience that transmitter systems can be adjusted to reject returnng reflections in many cases. Reg used to explain such rejection by an assumed very high transmitter output impedance, if my recollection is correct. If I misquoted Reg in any way it is unintentional. I disagree with the common opinion that classical plate resistance has much to do with transmitter output impedance. In my opinion, output conductance is proportional to the switched-on time of the final amplifier. Conduction angle controls impedance, which is much lower than plate resistance.

So why doesn`t the transmitter take back reflected power? The impedance bump is needed as a catalyst to cause a re-reflection. The re-reflection is as my professors said over 50 years ago due to the fact that the transmitter already has a surplus of energy. Energy always flows on a line from a surplus to a dearth, and not vice versa.

A tapering charge battery charger undergoes an amperage subsidence as a battery becomes charged. Even were the charger another battery as in the case of a jump-start, energy doesn`t flow from a lower potential battery to the higher potential battery.

A-C sources behave much the same. The greater-magnitude source outsupplies the other and determines the direction of current flow when the sources are facing-off against each other.

Best regards, Richard Harrison, KB5WZI

Maybe, but IIRC the FCC, along with the FAA, FEMA etc. etc. operate
extensive HF communications systems. It seems unlikely that a source of
such serious potential interference to their own communications would be
authorized?

Anyone who can obtain a copy of Arnold B. Bailey`s "TV and Other Receiving Antennas" can turn to page 158 to see a diagram of how waves interfere. Interaction between components of the same signal from two sources are shown in the figure to produce a combined signal which varies regularly with the height above the earth. This has a corresponding effect on the signal received by an antenna placed at a particular altitude.

The average signal at all altitudes is the same as if there was no interference. But, that is because the layers of strengthened signal are exactly offset by the layers of reduced signal strength.

Let's say we have two sources each equipped with a circulator and load resistor. We'll call such a source an SGCR (Signal generator equipped with a circulator and load). We set up the following experiment.

100W SGCL#1------------50 ohm lossless coax-----------50W SGCL#2

Seems to me that the 100W from SGCL#1 will flow unopposed and dissipate in SGCL#2's circulator load resistor. Seems to me that the 50W from SGCL#2 will flow unopposed and dissipate in SGCL#1's circulator load resistor.

In other words, the forward wave has no effect on the reflected wave and vice versa. There is no face off.

Now consider a normal system.

100W SGCL----------50 ohm lossless coax----------291.5 ohm load

50W will be reflected from the load and flow unopposed back to the circulator load resistor. There is no face off. Unless there is an impedance discontinuity, forward waves have no effect on reflected waves.

:-) Which reminds me. At the shootouts we subtracted reflected power
from forward power to yield the power to the antenna. If reflected power
doesn't exist, why did we subtract it?

I assume it applies to waves interfering in 3D space which is quite different
from waves interfering in the 1D space of transmission lines.

Well be it right or wrong here is what I did.

Installed an Al pop rivet in the tubing,

Soldered the tubing in place with some stuff called Alloy 5. I got it a
couple of years ago to fix a radiator, worked good but forgot I had it

Tapped the rivet for a #6 screw and applied a little Noalox I got from work

Weather proofed it with vynil and rubber stretch tape.

We will see How t does.

The BPL NOI has now moved to the second stage where reply comments can be submitted to the FCC.

Below are links to the comments from the cretins who want to flood our shortwave with interference.

IMPORTANT to read and tell the FCC what is wrong with their comments - many dismiss the interference issue without any data.

A huge amount of data has been submitted to the FCC that proves beyond all reasonable doubt that BPL is a gross polluter but more submissions are needed.

Please post comments and thoughts to this thread to provide ideas for other submitters.

From the arrl's 2-color letter to me on this subject, the money goes
to...

. monitor BPL comments being filed with the fcc

. legal counsel preparing response to the fcc's "notice to
inquiry" to gather public comments on BPL

. arrl lab is preparing tests to show how BPL would adversely
affect amateur radio

1 is positive (already filed comment)

One babbled about a "slur on the folks who live in rural USA",
forgetting that the vast majority of Internet traffic is comprised of
illegal mp3 downloads, Internet phone traffic, mass spam e-mail and porn
browsing, i.e. pure garbage traffic. Did I insult anyone? I really don't
give a flying fuck. I want my ham radio.

More than one wondered about the reliability of the 60 dB figure,
stating that, if it is correct, other commercial users would be
affected. Here's why they won't be:

To begin with, unlike amateur radio, none of the other radio services
are weak signal users. Whereas in ham radio, DX-ing is more than a rule
than an exception, commercial services aim for reliable, strong signal
communication. Therefore, while even as little as a 20 dB noise increase
(low enough for you, Art?) effectively prevents SW ham radio usage,
commercial users will barely notice it.

An overwhelming majority of SW ham radio stations are located in urban
areas with a high density of low and medium voltage power grids.
Military installations, otoh, are typically found in isolated
rural/suburban surroundings where they have a full control over (not)
allowing BPL into the bases. Btw, high voltage cross-country power lines
will not carry BPL, remember? There is fiber optic already in place for
that.

BPL is going to be delivered all the way to your power outlet, as well
as to your next-door neighbor's power outlet, and to every single power
outlet of every single resident in your city or town. Think you have a
hard time from your neighbor's electric toothbrush pwr supply? You ain't
seen nothing yet.

FAA does not use SW, afaik, so they couldn't care less. Ship to shore? What ship to what shore? They use satellites. Navigational? Nobody navigates downtown Los Angeles or in Manhattan. Any SW navigation is done thousands of miles away from the power lines. Who's left? Some governmental agencies that will solve a problem by increasing their budgets to allow for stronger transmitters and longer antennas?

The only way I see this being resolved is if there's enough RFI obliterating all of Rush Limbaugh's AM channels. Only then will FCC listen, because they'll have to.

That doesn't mean we have to go down without a fight. In order to fight, ARRL, the *only* American ham radio organization, needs money. However, if you'd rather cut off your nose to spite the face and pretend a turd is not in the punch bowl, it's your funeral...

Message-ID: <b64qgv876u17b3ilo48jsmuo06jq41g0jf@4ax.com>
Source record: 112937

Hi all.

I've got a 70 cm Yagi which is to be matched to a 50ohm feedline, feeding a 70cm repeater (5MHz split).

The Yagi has an impedance of 12.7+j0.8 (so 4NEC2 tells me).

What are appropriate matching systems to give me the best matching so that the Tx-Rx duplexer peforms up to its bandpass and notch specifications.

Thanks

MikeN

Again, I also wonder about ground loss. If the amount of ground loss
is high, it's ratio against coil loss is higher. A lossy coil might
not be much of an impact. But a low loss ground system would make a
lossy coil show up more being the ground loss is a lower part of the
total.

I agree with this part for most cases.

This means that
> a standard Hustler setup is louder than any "Screwdriver" or "Bug Catcher"
> unless they have more than
> 4½' of mast below the coil.

But, this is just pure finely ground sandwich meat. In the cases where
I tested, I never saw a hustler coil even approach my homebrew coil or
any other equal size coil for that matter, and at that time, my
homebrew coil was only 2 ft above the base. I tested the hustler on a
3 ft solid mast. It was waaaaayyy down. But they also use those stupid
short stingers, and hence use more coil windings than they really
should. Hustler is a special case... Also, note the test results
Cecil just posted...His results using the hustler seem to match mine.

We confirmed that in Fletcher, too. As an
> example, for 80M, a 9ft. top loaded mast was down 20.5db from a full quarter
> wave, both measured on the test stand. The base loaded 9 ft. mast was
> 36.5db down, a difference of 16db. BTW, the same mast loaded with a Smart
> tuner or Icom AH-4 was 44.5db down. Results are worse on 160.

I assume the 9 ft top loaded ant was the hustler...??? I notice they
don't mention the center or near top loaded bugcatcher coil in
comparison...Sure, a base load is going to be down...

> Seems that Hustler tried to "match" the low band resonators by introducing some
> extra loses in their loading coils. I rewound the resonators with 1/4" copper
> tubing (20 and up) but in view of W9UCW findings maybe there is good compromise
> between ugliness and performance.

I think the 1/4 inch tubing is overkill. Really , I think anything
over about 2 mm wire size is starting to be overkill considering the
increase you get. But, I am not a fan of hustler coils. I won't use
them. All the antennas I've made using those coils were "dummy loads
on a stick". That includes the 80-10 multiband vertical I tried that
used those resonators.
I've been thinking about the disparity some seem to see in coils. I'm
starting to think it's differences in ground loss. The less the ground
loss, the more a lossy coil will show itself. Enough loss, anything
might seem ok... MK

May I modify your experiment slightly? Change SGCL#2 to produce 100W.
Restating your explanation for the new experiment:
"Seems to me that the 100W from SGCL#1 will flow unopposed and
dissipate in SGCL#2's circulator load resistor. Seems to me that
the 100W from SGCL#2 will flow unopposed and dissipate in SGCL#1's
circulator load resistor."

Let's also make the 50 ohm lossless coax long enough that we can
find a voltage maximum. At this voltage maximum the current is 0,
always.
Assuming that P = V x I, the power is 0, always.
This seems to be at odds with explanation that SGCL#1's power is
dissipated in SGCL#2's circulator load resistor since there is no
energy flowing at the voltage maximum.

The obvious (and probably controversial) answer to this
inconsistency is that the power dissipated in CL#1 originates
in SG#1. Similarly for SGCL#2.

To further the experiment slightly, whenever a conductor in a circuit
has 0 current, the conductor can be cut without changing a thing.

Let's cut the coax at the voltage maximum (where the current is 0).
Nothing changes. The voltage and currents remain the same every
where. The powers remain the same everywhere, and yet there is no
longer a path from SG#1 to CL#2. The power being dissipated in CL#1
must be originating in SG#1.

Comments and corrections invited.

I don't think we need a conclusionary synopsis Zoran, I believe just about everyone here knows full well how to read.

Did you ever stop and consider that because the responses to your original post were such, that perhaps the whole BPL matter is the usual ARRL exacerbated hyperbole?.....In the old'en days they called it "Much ado about nothing".

Keith wrote:
"Assuming that P = VxI, the power ia 0, always."

Power is not zero on a line with a complete reflection because energy is moving at a joules per second rate. Power delivered to the line may be near zero in the steady-state.

There is no variation in power flow in either direction on a lossless line. SWR is an apparition. VxI in only one direction gives the power in that direction. A directional coupler is used to enable a proper in-line determination.

In Cecil`s example of senders feeding matched loads from opposite ends of the line, there are no reflections, but a directional coupler may be needed to separate energy in a particular direction.

Keith is correct that for some purposes the second of Cecil`s equal-power sources at opposite ends of the line could be replaced by a complete reflection. The power returning to the first source circulator would be the same as that from the second source, but would result from reflection.

Current and voltage only go to zero in an SWR pattern produced by a complete reflection. A zero-point in an SWR pattern does not indicate zero power flow in the line, though it may indicate zero power delivered to a load.

Zeros in voltage and current SWR waveforms are 180-degrees out-of-phase with each other. When there is a null in one pattern, all the energy is residing in the field represented by the other waveform. The energy did not disappear. So, you can`t disrupt a transmission line at a zero without effect in most cases.

Best regards, Richard Harrison, KB5WZI

Nope, a directional coupler can still separate out the forward
and reflected waves even at voltage and current nulls. Remember,
those voltage and current nulls are only a 'dl' in length as 'l'
approaches zero. Superposition of two waves traveling in opposite
directions has no effect on the individual waves. There are no
reflections except at an impedance discontinuity point which
doesn't exist in the example.

> Let's cut the coax at the voltage maximum (where the current is 0).
> Nothing changes.

Of course something changes. You have introduced an impedance discontinuity
where none existed before. The forward wave is 100% reflected at
the cut point and of course, the reflected power is dissipated in
the source's circulator load resistor. If you make the two sources
one Hz different in frequency, you can easily observe what happens
when you cut the line. Otherwise, it's the old steady-state Catch-22
coverup in action. :-)

Yes, but there is no face off between forward waves and reflected waves. Reflected waves flow unopposed back to the circulator load resistor where they are dissipated. Forward waves can affect reflected waves only at an impedance discontinuity where reflections and re-reflections can occur. Reflected waves can indeed flow "back up the fire hose" unopposed by the forward waves.

These systems, as well as military HF systems, usually operate in relatively
strong signal
environments. A lot of ham HF operation (especially DX chasers like myself)
try to work with
very low signal levels. Hams are possibly the only HF users in this
category. It seems likely that
the proposed BPL operation could substantially hamper weak-signal operation
while not really
impacting strong-signal operation.

I think the threat is quite real --- an yes, I did file a comment (although
it was a rather small one).
And yes, I am sending a contribution to the ARRL---it seems they are
fighting as best they can.

Source record: 112951

The ARRL Antenna Book (19th ed.) has an interesting design on p 6-32 for a 40M sloper that could easily be scaled to 20M. Measurements show the 40M version providing up to 20dB f/b and about 4 dB forward gain. The rear null can be positioned. The antenna would require a center support about 35 feet high for 20M. Five dipoles slope away at a 30 degree angle. The feedpoints are conected to a switchbox containing DPDT relays which are used to select the active dipole and position the rear null. The others serve as reflectors. Anchors for the five 20M slopers would fit in a circle about 35 feet in diameter. The article doesn't say anything about radiation angle. It does explain how the antenna can be constructed with less wire and no relays for a fixed direction.

I would be interested in the experience of anyone who has used this antenna.

From: Myron <msteir@charter.net>
Message-ID: <vgr63g2nkus462@corp.supernews.com>
Source record: 112956

I just purchased an Icom AH4 antenna tuner and intend to use it to feed a 28 foot length of wire in a narrow attic crawl space.

I know the tuner needs to be grounded and wonder whether a ground wire connected to an AC outlet ground is effective somewhat as an RF ground in this circumstance. I hesitate calling attention to any antenna wiring by running a heavy wire down the outside of the condo.

The other alternative would be to try and load a 28 foot dipole using one side (14') connected to the ground on the tuner. I just don't know if this setup would load well on too many bands.

Anyone have any ideas?

I have a balun with no identification on it but I'd like
to know what kind it is. Here's the info:

All coils are wound on a common toroid core.
One antenna lead makes 9 turns and is connects to the coax ground.
The other antenna lead makes 27 turns and is connected to the
coax center conductor.

Looks to be about #10 enameled copper wire.

Using the values above, calculate the rate of flow of energy equal to
V*I. That's how much energy is involved in your dilema here.

> It seems that everything you don't know the answer to is a
> non-sequitur. I fully understand your attitude.

Another one of your technical remarks?

>this circumstance.

Well, it'll serve as an RF counterpoise and so it may let you tune up
OK. It won't actually hold the tuner case down near ground very
well... the wiring is too long and too indirect to serve as a really
good RF ground. Also, you'll end up with a fairly hefty amount of RF
current flowing in your condo's ground wiring - much of this will
couple over into the hot and neutral, and you may end up with
substantial RF voltages appearing on the chassis of any "grounded"
equipment plugged into the mains on this circuit. This could very
easily lead to RFI/TVI problems, or to people being "bitten" by RF on
their TV or stereo. Probably not a good idea.

>The other alternative would be to try and load a 28 foot dipole using one
>side (14') connected to the ground on the tuner. I just don't know if this
>setup would load well on too many bands.

This is probably safer. You could try several things to improve the
load-ability:

- Add a choke balun where the coax reaches the tuner (just take 8-10'
of the coax, and wind it into a loop 8-10" in diameter and use
tiewraps to hold it together). This will help maintain balance
between the two sides of the dipole.

- The dipole wires don't have to be straight. If you zigzag each
side of the dipole back and forth across the width of the attic
space a couple of times you can probably increase the length of the
wires significantly, and improve the tuner's ability to load up the
wires onto the lower-frequency bands.

Hey! Is this the new 'strategy' to get around PRB-1??

That is 'Create so much HF noise that the hams will close up shop and
take those ugly things down.'

OK, I apologize for any and all angst that I have caused you (or anyone else on this newsgroup). My Dad and my best friend both died this year and I have been in a foul angry mood for most of the time.

I would like for you and me to lay our personality conflicts to rest, but based on your past actions and reactions, I really don't think you are capable of being a gentleman. I have a lot of friends with which I differ on technical issues, but you are the only one of them who has ever threatened me. Please prove me wrong about my opinion of you. I have removed your address from my email kill file.

I've simply used a folded-dipole (equal diameters for the two
sections) driven element in similar cases. That should give you very
close to 50 ohms. It's balanced, so use a 1:1 balun to get to 50 ohm
coaxial.

Cheers,
Tom

You can find books with graphs of dipole impedance versus length and wire diameter that will give you a lot of appreciation for what happens. You can, of course, use a program to generate such graphs yourself, but it's already been done for you. I've found it helpful to look at what happens to "short" antennas, as well as at resonances at both odd and even multiples of a half-wave, and at points in between the resonances. I've particularly liked the graphs (and explanations) in the "Antennas" chapter of King, Mimno and Wing's "Transmission Lines, Antennas and Waveguides" book. Since the graphs are showing the value of a complex dependent variable versus two independent real variables, it's nice that they are presented in several different formats. It might be fun to put the data into a modern interactive graphical presentation program to play with, but the old 2-d plots can still tell you a lot.

The feedpoint resistance changes a lot for wire diameter changes with a full-wave dipole, but as others have noted, not much at all for a half-wave. You'll see similar things at other even multiples and odd multiples of a half-wave. Of course, the same thing applies for quarter, half, 3/4, full, etc. wave elements feed against a ground plane.

Cheers,
Tom

(Aside: Thanks to Roy and Kevin for their postings on this subject!
I'm especially glad to see that Kevin still checks in here
occasionally.)

As an experimentalist, I'd suggest simply commandeering the antenna
into which you're feeding the 100 watts for long enough to do a
network measurement between the antennas. Since you really only care
at one frequency, simply reduce the transmitted power to 1W, for
example, for long enough to find the power at the appropriate point in
the active antenna chain. It's a linear system, right? So 100 times
the input power will result in 100 times the "output" power. All that
seems much easier than going through the intermediate step of
measuring field strength...and since it sounds like you may be within
the near field of the transmitting antenna, you may not be accurately
characterizing the field strength in any event.

Cheers,
Tom

> I would like to use coils instead of stubs, easier to make enclosures
> and mounting points.

Surprised you haven't gotten any other answers on this yet.

Suggest you look for a program that will tell you the self-resonant
frequency of a solenoid coil and use that to _estimate_ the coil you
should use. Try to make some measurements with that and with some
coils a little longer and a little shorter, and also for comparison,
against a measurement of just a simple quarter wave (assume you want
to run it against a ground plane).

Consider also that you could use a coaxial phasing stub: make one of
the elemens from coax whose center shorts to the outer an electrical
quarter wave away from the end; outer is the radiator of that section
and the inner connects to the end of the other section.

But I'd also suggest you read the part of the "Antennas" chapter in
King, Mimno and Wing's "Transmission Lines, Antennas and Waveguides"
that talks about phasing stubs, and suggests that coaxial stubs (and
by implication, phasing coils) do NOT work as well as stubs
perpendicular to the axis of the antenna.

I'm personally partial to the "coaxial collinear" construction in
which transmission line characteristics ensure proper phasing of the
feedpoint voltages between each pair of elements.

Cheers,
Tom

I am not trying to be derogatory just trying to be reaslistic
but my logic may be incorrect!!!
60db I suppose could equate to an S9 signal. Is this in error?
Are we saying to the FCC that in all cases the noise will be at
a S9 level? Say the proponents Prove that the noise level will
never exceed S1 and state that the ARRL is over reacting !
If they also state that this benefits the majority of internet
users (or total population)in that it can reduce costs by half,
then ham radio would be in a very sad position.
Now I have heard it stated that from 14 thru 30 Mhz the actual
noise level is far below the normal radios thresh hold, so what
will be the TRUE noise level that we would have to compete with?
If it was declared specifically what 'S' noise level increase that
we would have to contend with on EACH band rather than the inuendo
of S9 level, we would be better positioned to determine whether we
were complaining for complaining sake and frittering away any
possible influence we do have for the future.
If we are to use our number strength wisely for the benefit of
the hobby then it would behoove the ARRL to be very specific
with respect to the possible danger so that the label of
obstructionists will not be aplied at a future date.

> wrong about my opinion of you.

Well, that didn't last very long. I have never threatened you. I don't
threaten people. Every one of my personal friends knows me as a truely
gentle man. I find it difficult to see how I could ever change your
opinion about anything.

As you may recall, I was virtually your only supporter on this newsgroup
when I joined this quest. I expressed to you my opion that your
approach, if correct, was simple, elegant, and beautiful! We seemed to
share that enthusiasm in this search for a detailed explanation of the
phenomenon. We shared skepticism about reflections from virtual shorts,
and agreed that reflections occur only at physical discontinuities. I
had discussions with several of the regulars here on the issue, lending
support to your point of view about the interference phenomenon. I very
much enjoyed that for once we had a common interest and point of view.
I've corresponded via email with Steve Best, Walter Maxwell, and others
on the issue all prior to having seen part 2 of your paper. After
reading part 2 though, I expressed to you that I had reservations about
the reversal in the direction of energy described in your paper. I
investigated further, and also asked a few of the professors at UC
Irvine to consider the problem. The bottom line turned out that there
is no physical or mathematical way for such a thing to occur - absent a
reflecting media. You wouldn't hear of it. At that point you saw me as
your adversary, and began treating me as such. Since then you've called
me delusional and impugned my intellegence at almost every opportunity.
And yet throughout this whole thing, I've had only one interest. It
is the very same one we both shared at the outset, to discover the
truth. I've conveyed that truth to you to the best of my ability.
And why do you think it is that, through all the insults I've continued

to try to convey it to you? It's because I would like to get back to the point once again where you and I share a common viewpoint. That's it. The angst on my part stems from the fact that someone whom I respect, continually finds the need to insult me. Most of the time you'll find I've refrained from commenting on the insults and have simply deleted them. Over the last couple of days however, I spent some time trying to illustrate what that looks like from my point of view. And now we find ourselves here.

Of course I appologize for having caused you angst. It was never my intention to cause angst! And it shouldn't have done so. It should only have caused you to reconsider your point of view, and consider another one. I honestly don't believe you have been able to do that - for whatever reasons. Perhaps the case is not unlike that of a scientist who has too much career invested in a particular theory. I don't know. All I know is this is the only less than amicable relationship I have in my life, and I truely wish it were amicable.

> I have removed your
> address from my email kill file.

I appreciate that courtesy. It's not something I ever thought was necessary.

Yes, it does, which is not at all if we already know the
reflected irradiance which is a given. If the reflected
irradiance is a given, you don't need to know the index of
refraction of the glass. In fact, if it is unknown, you can
calculate it from the given reflected irradiance.

>>>> 50V at zero degrees and 1A at 180 degrees = 50W
>>>> 50V at 180 degrees and 1A at zero degrees = 50W

> :-) Yes, very technical. If a math question was posed, I must have
> missed it.

It ain't rocket science. What is the superposed sum of the
two above waves? What happens to the intrinsic energy pre-
existing in those waves before they cancel each other?

> Using the values above, calculate the rate of flow of energy equal to
> V*I. That's how much energy is involved in your dilema here.

The rate of flow of energy has to be 100 joules/sec since the energy
in those two waves cannot stand still and cannot be destroyed. We
already know that the energy in those two waves joins the forward-
traveling power wave toward the load.

Art Unwin KB9MZ <aunwin@insightbb.com> wrote:

>60db I suppose could equate to an S9 signal. Is this in error?

No, I don't think so.

>Are we saying to the FCC that in all cases the noise will be at
>a S9 level?

They're saying that an Access BPL system, based on the technologies
which have been proposed (and tested in other countries), would induce
enough energy on nearby amateur-radio antennas (e.g. a dipole located
within 30 metres of the power line), to raise the broadband noise
level at HF frequencies on the rough order of 60 dB above the ambient
noise levels which are now generally present in urban areas.

> Say the proponents Prove that the noise level will
>never exceed S1 and state that the ARRL is over reacting !

As far as I've been able to tell from reading the various materials,
the BPL proponents here in the U.S. haven't made this sort of claim,
nor have they performed any significant number of actual field trials
to measure interference and noise levels.

They seem to be evading or ignoring the issue.

>If they also state that this benefits the majority of internet
> users (or total population)in that it can reduce costs by half,
>then ham radio would be in a very sad position.

I don't think they've made that level of claim either.

> Now I have heard it stated that from 14 thru 30 Mhz the actual
> noise level is far below the normal radios thresh hold, so what
> will be the TRUE noise level that we would have to compete with?

You have, I think, heard incorrectly.

What I have heard and read in the past... and what I've read in the
noise specs posted in the ARRL's response to the FCC NOI - is that on
the HF bands, the noise floor is dominated by atmospheric (QRN) and
man-made (QRM) noise, *not* by the noise floor of the receiver's own
electronics. The ambient noise level most of us face today is many dB
up *above* the radio's threshold, not "far below".

It isn't until you get up into the VHF bands that the receiver's
self-noise becomes equal to, or greater than the ambient noise level.

That's the problem with BPL. It's not just that the noise levels it
generates would be quite a lot above the noise floors of our
receivers' electronics - they'd be well above the typical ambient
"band noise" levels present today on most of the HF bands.

In other words, BPL *will* bury a lot of the weak signals we can
receive today, and will bury 'em deep.

>If it was declared specifically what 'S' noise level increase that
>we would have to contend with on EACH band rather than the inuendo
>of S9 level, we would be better positioned to determine whether we
>were complaining for complaining sake and frittering away any
> possible influence we do have for the future.

So GO READ THE ARRL's RESEARCH, won't you? As I recall, the 121-page
analysis they posted a couple of days ago shows the typical
receiver-self-noise and typical ambient-band-noise levels in each of
the HF bands, and also shows the noise level which could be expected
to be created by an Access BPL system running on power lines located a
typical distance from an urban amateur's HF antenna.

They've done the research, Art, based on what appear to me to be very
reasonable (and probably conservative) models of BPL behavior,
powerline configuration, and radio sensitivity. The data's out there.
Go look for yourself.

> If we are to use our number strength wisely for the benefit of
>the hobby then it would behoove the ARRL to be very specific
>with respect to the possible danger so that the label of
>obstructionists will not be aplied at a future date.

It appears to me that they have done so.

Here's an interesting reply to one of my postings on
sci.physics.electromag:

> Cecil said:
>> Seems to me that destructive interference event occurring in the direction
>> of the source feeds energy to the constructive interference event occurring
>> in the direction of the load.

The reply was:
Yes, just so. In fact, the phase change/non-change when the waves are
reflected/transmitted by low-to-high or high-to-low interfaces ensures
that this will always happen - if in phase on one side, they must be out
of phase on the other.

Which is exactly what I say in my article.

Of course not! But if you live in an area criss-crossed by active lines, and have the sigs coming into your house you can expect some pretty strong interference.

> Say the proponents Prove that the noise level will
> never exceed S1 and state that the ARRL is over reacting !

I will accept Ed Hare's (and the other testers) figures. You could if you like come up with some of your own.

> If they also state that this benefits the majority of internet
> users (or total population)in that it can reduce costs by half,
> then ham radio would be in a very sad position.

It isn't just hams who use HF. Some homeland security type services do also.

Would you ever design a system that spills rf all over the place like this? Why on earth should we shield televisins, radios computers, etc if we are going to put a huge antenna up to negate all that shielding?

There are good ways to get a broadband signal into a person's house without messing up everything else.

Adn why should the internet have priority over everything else?

That's pretty sappy, Cecil. For one thing, although you might care about that, I wouldn't presume to think you'd care about it. For another it's not my MO so, yes. But I've saved all of our correspondence, so if you can quote a date and time, I can look it up.

As I've already said, the exchage was a request on my part that you treat me like a friend - as in trying to establish a friendship with you. To put it into context, it was right after you began taking an adversarial stance in our conversations. How you can take that as a threat, I'll never know.

Interesting that's the only thing you had a comment on.

The waves themselves are indeed identical, i.e. you can't measure a difference between them on a transmission line. But one might indeed be transferring energy while the other is not. For example, take a length of 50 ohm transmission line with a short at one end. Think about this circuit with and without a circulator at the source. With the circulator in circit, energy is transferred from the source to the circulator load. Without the circulator, the source transfers no energy to a load. If there are no re-reflections from the source, is there a measureable difference?

> How does the wave know ahead of time whether it is going to encounter a
> dissipative load or not? It obviously cannot know ahead of time so all
> waves with the same V and I in phase carry the same amount of energy.

This is a misconception on your part. I don't claim anything has to know anything. That is your claim, and I don't agree. I think it's silly.

> A wave about to encounter a dissipative load or the same wave about to be
> canceled carry the same amount of energy.

They have the same potential to transfer energy. The do not necessarily transfer that energy. That depends on boundary conditions.

> The wave gives up that energy in
> both cases. In the first case it gives up its energy as heat. In the second
> case, it gives its energy to the constructive interference.

I understand that is your theory. I even like the sound of your theory. But you need to understand that it is only your theory. It is an unproven, and unsupported theory. I've tried to come up with support for it, but find none. Yes, the energy which would have been reflected does appear in the transmitted direction. We know this from conservation of energy - energy incident equals energy transmitted plus energy reflected. What does not appear to happen is all the bouncing around you describe.

It can be shown that at the first boundary, two reflected waves destructively interfere, producing zero reflected energy. It can also be seen at that boundary that the two waves traveling in the forward direction yield all of the forward energy due to their constructive interference.

I understand that if you take the interference term and change its sign you get the same number, and its not just a coincidence. Yes, you can say the amount cancelled in the reflected direction equals the amount of enhancement in the forward direction. But that doesn't mean energy had to turn around in order to accomplish that. That would only be true if energy were indeed traveling in the reverse direction to begin with. When we realize it's not, there's nothing left to account for Cecil. There's no conservation of energy problem to solve. It's all there, just as it says in the physics books, and enegineering books as well. If you want to believe that energy bounces all over the place like, so be it. Just don't expect to be able to sell paraphysical phenomena as science.

But as I've tried to tell you many times before, when you can show that Poynting vector solution changing direction solely as a result of destructive interference, you'll have a case - and my vote. Until then, it looks like a non-starter.

Looking for suggestions for flagpole design for Florida Mobile Home Park where flagpole OK, antennas not OK. Thought of the Diamond shaped flagpole configuration as a (CAP) top-loaded vertical. Anybody tried this? Note, my ground is probably terrible, and as a stealth antenna, radial (maybe 2) must be installed after dark Looking to run about 100W.

Dave,

I will definitely add a choke balun.

How much zig zagging do you think I could get away with without introducing factors that would seriously degrade performance? My attic crawl space is about 3 feet wide, 4feet high pitching down to the floor and 28 feet in length. I imagine I could easily fit a 33 foot dipole in that area to work 20M.

Thanks for the info.

Myron

How can two waves that are identical possibly be doing different things.
It doesn't make any sense at all. Waves cannot exist without intrinsic
energy!!! If any wave is destroyed, it gives up its energy. There is
simply no other place for the energy to go.

>> How does the wave know ahead of time whether it is going to encounter a

>
> This is a misconception on your part. I don't claim anything has to
> know anything. That is your claim, and I don't agree. I think it's silly.

That the wave has to be smart falls out from your assertions. Your waves
appear to exist without intrinsic energy so they have to know ahead of time
whether to exist without energy or not. Only a wave existing without energy
could be destroyed and not give up any energy in the process.

> But you need to understand that it is only your theory. It is an
> unproven, and unsupported theory. I've tried to come up with support
> for it, but find none.

Please reference the cross-posting from sci.physics.electromag. Somebody
predicted that those guys would tear me apart. On the contrary, they
tend to agree with me.

Those reflected waves not only destructively interfere, they are
destroyed so they MUST give up any intrinsic energy in the waves.
Nothing else is possible.

> Yes, you can
> say the amount cancelled in the reflected direction equals the amount of

Huh??? "Reflected" to "forward" isn't a turn around? Can I have a hit
off whatever you are smokin'? :-)

> That would only be true if
> energy were indeed traveling in the reverse direction to begin with.
> When we realize it's not, there's nothing left to account for Cecil.

If reflected energy from a mismatched load is not traveling in the reverse direction, pray tell what direction is it traveling in? I can see you haven't referenced the reflected power flow vector.

> There's no conservation of energy problem to solve.

There certainly is in your scenario. The reflected energy doesn't ever change directions but it somehow joins the forward wave anyway. Can you spell B-A-F-F-L-E-G-A-B? We know reflected energy is traveling rearward from a mismatched load. Your mantras cannot change that fact of physics.

Try the old Frank Jones VHF handbook ,he was a "6", (if you can find one) he did more than a few colinears (includeing an 18 El one for 432) can't renmember his call, and this NOT modern, (from the 60's) but what you are essentially trying to do is: from top of element, to bottom of NEXT element, create a 180 deg phase shift! can do that with a out of (radiation) plane 1/2 wave long (like the center piece of a cushcraft ringo), or RESONATE CIRCUIT (but, this if high "q" can cause problems, this is also how the multiple stacked 1/2 wave sections on commet, and many commercial antennas work! those configured out of stacked , center conductor to shield, and vice versa coax pieces , all the way to the top, (EXCEPT at the top, they shorted together, and hit a 1/4 wave rod)! been in handbooks for years--

I'd think that you could zig-zag the wire back and forth at an angle
of 45 degrees to the long axis, a foot or two above the floor, without
causing substantial degradation of performance. If you don't end up
needing to zig-zag that much to fit the 33 feet of wire into 28 feet
of space (and you probably wouldn't), zig less frequently!

Take a look at the discussion at http://www.cebik.com/zzdd.html for
some further ideas.

I imagine that your antenna's performance is likely to be set mostly
by the amount of power you can use without causing RFI/TVI due to the
strong RF fields in close proximity to household wiring. The slight
reduction in antenna efficiency isn't likely to matter very much.

Excerpt from the ARRL Release:

"Studies appended to the League's comments suggest received signal levels of BPL broadband noise at typical amateur stations would be anywhere from 33.7 dB to 65.4 dB higher than typical ambient noise levels in the worst-case situations. "BPL cannot be deployed using amateur allocations in the MF, HF and VHF bands without severely high interference potential," the ARRL reiterated. "

DD, W1MCE

The ARRL has submitted 120 pages of comments including analysis and related data.

The BPL grid includes power distribution on medium power lines right down to the 240 volt feed that comes right into your house!! Is that close enough to create a +60 dB noise level??

DD, W1MCE

look for an old article called "beer can baluns ", in QST, maybe also,in some of their handbooks. consider, that you need a 1/4 wave length lonf piece of 25 ohm coax (if you build with no dielectric, will be true 1/4 wave length, no velocity factor) this will be a "sleeve, or "choke" balun (to acheive a balanced feed, and will provide you a match under 1.6 to 1! (assuming your impedence formulai is correct! Math is for your balun Zo (line required) = Zo (in), Times Zo (out), and then take the SQUARE ROOT RESULTS OF IT! , (and with the small reactive component, should be insignificant to the calculation) Good Luck-- Jim NN7K

Dave,

Thank you once again.

I'm going to run a maximum of 100W with my Icom 725 and assume (hope) that the power level is low enough to avoid problems.

The website you directed me to is pretty darn nice. I've done antenna searches on Google and never came across this worthwhile info. I'll try to digest the material.

I wish the ARRL antenna handbooks would explain things as simply. When I've used their manuals for reference (I have a fair library), I find that my eyes begin to glaze over. I bought their "Stealth Radio" book, hoping for ideas, but that was way too basic. I did come across some useful websites using Google, but alot of the information was duplicated so there was not as many useful ideas as I had hoped for.

You've been the biggest help.

Evan- done that myself, as a radioman , on more than a few occasions! they might call it blind mound, but lots of quicksand in these modern vehicles! Tale it you Centered on roof , drilled a hole and, there are several probs (sepending on vehicle) to get coax down, and /or clearance for the mount. if auto, or pickup, there is a rib that runs front to back , and (assumeing that a headliner is installed, can be be hammered , with a screw driver to force it lower, by 1/4/3/8 inch, so you can manouver the fitting/coax into position. Blazers/Bronchos pose another problem, as the front seat area , is an opening that goes nowhere! best way I found to hide the install , is 1) there is a Second roof that must be penetrated (this kinda like a roll bar), but, then this also doesnt go anywhere! fortunatly, there is a rubber "coupling" to cause a seal with the fiberglass roof, and if you punch a hole under this gasket, can feed coax to passenger compartment, and then dress, under this rubber seal, all the way to the floor, and then to the radio, under the door ducts!. . sadly, at one time vehicles had prepaired ways tio get installs in, but that is NOT THE CASE TODAY! and, btw, tis violation of law to EVEN BLOCK those GAS BAGS, and they dont even telly you WHERE THEY HID THEM! I am still left quite confused by this. In the experiment proposed (a slight
variation on Cecil's), at a voltage maximum the current IS a constant 0 (or
similarly, at a current maximum, the voltage IS a constant 0). These 0 volts
and currents can be measured.

If we accept that instantaneous power is P = V x I, then at any point on the
line where the voltage or current is a constant 0, the power must be a
constant 0.

From the definition of power, it would seem that where ever the power is a
constant 0, the energy flowing must be a constant 0.

So I do not understand how energy can get through a point in a circuit
where the voltage or current is always 0, unless:

- instaneous power is not equal to instantaneous voltage times instantaneous
current (i.e. P != V x I), or
- even in the ideal case presented, V and I are never 0.

> Nope, a directional coupler can still separate out the forward
> and reflected waves even at voltage and current nulls.

It is a bit early to move to the complexity of directional couplers.
I am still stuck on how energy can flow through a point on the circuit
where the current or voltage is always 0.

Using instantaneous Power = Vinst x Iinst, the power at such a point
must always be 0, leading to the conclusion that no energy is flowing.

So how does energy flow through a point in the circuit where the voltage
or current is always 0.

Is it that Pinst != Vinst x Iinst?
Or is it that there is no point in the ideal experiment presented where
V or I is always 0?
Or have I missed something in the chain of reasoning above?

It is very easy to skip over my message if it annoys you. Just hit a
down arrow button. I wouldn't agree on the reading skill point, though.

> Did you ever stop and consider that because the responses to your original
> post were such, that perhaps the whole BPL matter is the usual ARRL
> exacerbated hyperbole?

Yes, I considered it for about a millisecond and then promptly dismissed
it based on my previous knowledge of the anti-League posts and feelings
from a small but vocal group of people. The only way you could get those
types on board against the BPL is if the ARRL took a pro-BPL position.
Then you'd never hear the end of it, and demonizing the League would go
on for years, like it has with no-code, for example.

> ....In the old'en days they called it "Much
> ado about nothing".

Yeah, sure. What, if I may ask, is your profession? If you are an
electrical engineer and you don't consider BPL (a dense, unshielded,
unbalanced grid of random-length wires carrying packets of digital
signals with all their harmonics straight to your shack) a huge
potential source of HF noise, then I don't know what to say. Have you
read on the subject? Have you seen the measurements from the field in
other parts of the world? All of this fails to convince you because you
know for a fact that this is just a conspiracy on the part of the ARRL
to swindle you for a couple of bucks?

Fine. Don't support it if you don't want to. Don't join the ARRL. Work
against it any chance you get. After all, CB has no representation and
organization and they've never been in a better shape, huh?

958. Rockwell-Collins PropMan 2000 - solution for issues with internet space wx data retrieval

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-11 01:45:18 UTC
From: "Carl R. Stevenson" <wk3cqth@wk3c.com>
Message-ID: <OEoPa.75$lL.7781@nnrp1.ptd.net>
Source record: 112904

For those of you who have the Rockwell-Collins "PropMan 2000"
propagation software ...

You may have noticed recently, as did I, that the program was no
longer able to correctly retrieve "space weather data" from the internet
that is used to improve the accuracy of its predictions and predict
"ion storms," etc. based on current solar/geomagnetic conditions.

The problem seems to be that the folks at NOAA have made some
changes in which GOES satellites are used for x-ray and proton
measurements, with the result that some files that PropMan looks for
either no longer exist (have been replaced with equivalent data in the
same format, but with different filenames, due to being sourced from
instruments on a different GOES satellite) or no longer seem to be
available via "GOPHER" ... and the directory names have changed
for access via http ...

After some poking around the NOAA website where the data resides
and hacking on the "propman.ini" file, I have come up with a propman.ini
file that works.

This new "propman.ini" file is available from my personal website at:

http://home.ptd.net/~wk3c

and may be freely used for non-commercial purposes by radio amateurs.

Placing this new propman.ini file in the same directory as your other
PropMan
2000 files solves the problems with ion storm warnings, etc.
(First, make a backup of your current propman.ini file by renaming it to
"propman.ini.original" or something like that ...)

There is ONE exception ... the USAF and NOAA have discontinued
the distribution of a file called "HFRP.txt" from which PropMan 2000
parsed the SSN data. This does not cause internet updates to fail, and
the SSN data is available from the following URL:

http://www.nwra-az.com/spawx/env_latest.html

Look in the row labeled NWRA SSNe: and pick the right-most value
(the data for the current day) and manually enter that into the SSN
box in your PropMan path dialog box and that will work fine.

I am in touch with the engineer in charge at Rockwell-Collins and they
appear to be working on considering a re-write of the PropMan 2000

parser to get the SSN data from the URL above ... I have suggested an
alternative approach that would not require changes to the existing
PropMan 2000 program and am awaiting a reply.

>Dave,
>
>Thank you once again.

You're most welcome. The real thanks go, of course, to the folks who write those various wonderful educational pages. I've learned a very great deal over the past year or so.

>I'm going to run a maximum of 100W with my Icom 725 and assume (hope) that
>the power level is low enough to avoid problems.

Ummph. You may have problems there.

Anecdotal evidence suggests that in a lot of residential situations, running more than about 25 watts HF is fairly likely to create a situation known as "fundamental overload" in nearby consumer-grade TV tuners and FM radios. The strong RF signal saturates the tuner electronics, forcing them into nonlinear behavior. It doesn't help even if your RF signal is perfectly "clean" and has no harmonic content (an impossible ideal) - even a pure signal will result in these TVs and other such devices misbehaving (herringbone displays, etc.).

Adding a high-pass filter at each affected TV set's RF input, and adding choke filters to the power cord and A/V cables, can help a lot.

The same is true for telephones. I know that when I key up a 20-meter PSK31 signal at about 20 watts, my wife can hear it on her telephone (I really need to add some ferrites) and my antenna's outdoors up at about 25'.

With an in-the-attic antenna you may need to keep power down to 5-10 watts to avoid interference.

That's the bad news. The good news is that cutting power from 100 watts to 10 is only 10 dB, which isn't even one S-unit on a typical amateur receiver. Under most circumstances it won't make a big difference in how audible your signal is. There's one particularly skilled operator in my area who regularly breaks CW pileups to South Pacific islands, running only a couple of watts, from an HF mobile rig in his car. [Maybe if I play around with this stuff for a few decades I might pick up a fraction of that skill... I should be so lucky!]

> volts and currents can be measured.

But they are zero only because of superposition. The forward current
is NOT zero and the reflected current is NOT zero. The fact that the
NET current is zero just means that all the energy moved into the
electric field at that point but it still exists.

> If we accept that instantaneous power is P = V x I, then at any point on
> the line where the voltage or current is a constant 0, the power must be a
> constant 0.

Nope, for standing waves, if the H-field is zero, all the energy is in the
E-field. If the E-field is zero, all the energy is in the H-field. The field
that is zero is undergoing destructive interference. The other field is
always undergoing an equal magnitude of constructive interference.

> From the definition of power, it would seem that where ever the power is
> a constant 0, the energy flowing must be a constant 0.

Nope, if the current is zero, the voltage is at its maximum value. You
cannot have a maximum voltage with zero energy.

> So I do not understand how energy can get through a point in a circuit
> where the voltage or current is always 0, ...

That's one of the problems with being seduced by the steady-state model. :-)
Look at the component forward and reflected waves and all will become clear.

There are two voltages and two currents. Sometimes they are 180 degrees
out of phase and their sum is zero. But those waves don't know each
other exists. Someone forgot to tell them that they aren't supposed
to carry any energy so they just keep on carrying energy.

> Using instantaneous Power = Vinst x Iinst, the power at such a point
> must always be 0, leading to the conclusion that no energy is flowing.

No *NET* energy is flowing but the forward energy and reflected energy
just keep on flowing, carrying an equal amount of energy in each direction.
In a transmission line with reflections, there are always forward and reflected
transactions. Please don't be seduced by the steady-state religion.

Thanks Sjoerd.

Two questions arise.

I'd thought earlier of using a 1/4 wave transformer, using paralleled
50 ohm coax to give me 25 ohms, which transforms the 12.7ohm antenna
to to 49, say 50 ohms, but isn't the DK7ZB match still an unbalanced
feed to a balanced radiator?

Won't this perturb the directivity?

Thanks

Given FCC head commissioner Michael Powell's basic orientation -- he
used to be a lawyer/lobbiest for large media company's, and he
recently has turned the whole radio industry over to the Clear Channel
folks -- where do you think he might come down in this controversy? I
suspect he'd be much more aligned with the BPL'ers than with a bunch
of crummy hams polluting nice neighborhoods with their antennae.

968. TA-33 Beam question

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-11 05:08:04 UTC
From: GS <greatsurplus@hotmail.com>
Message-ID: <6f61b2074b4a14c7f773cbf6144bac25@news.meganetnews.com>
Source record: 112912

Hello all,

Funny how things work. I have been trying to sell my Mosley
TA-33 beam and AR-33 CDE rotator. I bought them in 97
fully intending to put them up, but never got to it. Been sitting
in the backyard since then, on the roof of my shed, disassembled.
The rotator of course was in the house.

But after a few days of no local interest in it, I think I've decided
I want to keep it! I got it all out on the front lawn today, and
layed out all the pieces to match the assembly instructions,
and wow! It looked really cool and now I think I want to keep
it - I've never had a beam, so now I'm thinking I'd like to put it
up and see what it's like to work 20 with a directional antenna.

But all I have is the assembly part of the manual - how difficult
is it to tune? Can I prop it on a ladder on my lawn and tune
it 'on earth' using my MFJ antenna tuning meter?

And since I don't plan to install a tower on this particular whim,
can I get away with putting it on a short tripod bolted to the
roof on the second floor? Or is that a no-no both for structural
reasons as well as proximity to the composition shingles?

Any advice would be appreciated!

Dave WB7AWK

Dave,
Rather than setting the beam on a ladder to try to
tune it, stand it up so that it's pointed straight up.
The step-ladder thing won't get it even close.
As for using a tripode on your roof, it just depends
on how your house is built. Is it in good structural
shape? Built strong enugh to take the weight and other
stresses that will be present? Beats me! You'll have
to answer that.
'Doc

PS - If you decide to sell, I'll give you $20, you pay
shipping. After all, it's at least 7 years old. All
the electrons have leaked out of it by now...

>feed to a balanced radiator?
>
>Won't this perturb the directivity?

The same thought came to my mind when I read the DK7ZB pages this afternoon (it's a neat design idea and is going into my keep-this notebook!) Seems to me there might be a pretty easy way to deal with this.

A 1/4-wavelength coax transformer for 2-meter operation, using typical V=.66C foam-dielectric coax cable is going to be just about a foot long. I'd think that one could wind the pair of coaxes through a modest-sized ferrite toroid core a few times and tie-wrap the ends firmly into place, rather than just running them out along the boom and back. This should create a reasonably effective choke balun... something like a Reisert 1:1 style, but acting as an impedance transformer thanks to the paralleled coaxes. You'd get both the 12.7 : 50 ohm transformation, and the balancing, out of one package.

You'd probably want to wind only part of the impedance transformer around the ferrite, leaving a few inches to make the connection to the feedpoint (thus keeping the balun itself from coupling into the radiating element too badly).

Another possibility: in his book on baluns and ununs, Jerry Sevick discusses this basic sort of application, and suggests that a 1:1 balun of this sort can be used as an isolation transformer by putting it 1/2 wavelength back down the coax from the balanced-antenna feedpoint (a technique which he credits to one of Roy W7EL's articles). It seems to me that this would work equally well for one of these 1/4-wave-impedance-transformers-wrapped-into-a-balun. Mount it back behind the reflector, run 1/2 electrical wavelength of any convenient coax (or maybe open-wire line?) up to the antenna feedpoint, and it'd still perform both the balanced-to-unbalanced conversion, and the proper impedance transformation in that location.

So - does this make sense, or am I being stupid and missing something?

974. KLM or M2 KT34XA or KT36?? Please help me ID my new antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-11 07:08:30 UTC
From: ve7khzr@yahoo.com
Message-ID: <84965f10.0307102308.43f56d8e@posting.google.com>
Source record: 112918

I know there are some real antenna gurus on this group and wanted your help to ID an antenna I just picked up. First off, it's big, real big, well bigger than my MP-33. I know it's either a KLM or M2 KT34XA I think, but what's throwing me off is the boom. I thought, from the last KLM catalog I have, that the boom was split in half, right in the middle. The one I have is split about 1/3 - 2/3 and is heavy wall 1/4" AL pipe, 32' total. The elements are definately KLM as they have the shorting straps, not the machined ones like M2 use. Blue capacitor caps on the trap portion. I suppose someone could have built a new boom??

Anyway, my plan for now was to to try to use it as the KT34A, which was a very popular 4 el. 16' boom, then when we move, add the XA portion which is another 16' and 2 elements but the way this is configured, I will have to get a new 16' boom to use it as the 34. Can it be used like this without changing the element tuning? It's in pretty decent condx.

A few Q's. When did KLM shut down? When did they start using the "blue" caps. I hear there are "new" dimensions available for the element spacing and tuning. Are these posted anywhere or on someones web site? Could this also be an M2 or have they always used machined shorting straps?

I will take some pictures of the unit if it will help ID it.

Thanks folks. Appreciate the help.

Cheers!

Paul

> No they don't, and...

Changing the energy in a TEM wave to heat is obviously a transfer of
energy. Radiating TEM energy from an antenna is obviously a transfer
of energy. When TEM wavefronts are destroyed by wave cancellation in
a transmission line, they cease to exist and must therefore transfer
their energy somewhere. There is simply no other possibility.

At an impedance discontinuity match point with reflections, the
destructive interference energy is transferred in phase to the
constructive interference event occurring in the other direction.
Please see the "Mental Exercise" thread cross posted from
sci.physics.electromag

> What *exactly* is your definition of a "wave"?

"traveling wave - The resulting wave when the electric variation
in a circuit takes the form of translation of energy along a
conductor, such energy being always equally divided between
current and potential forms." i.e. P=|V*I| and Z0=V/I

If you're not a licensed ham, and by the sound of your post you're not, then it really doesn't matter what antenna you use because you wont be transmitting over that range anyway, will you....

If you are a licensed ham, then you should have the basic technical knowledge to know how to get an antenna to tune to the frequencies you need to use, and I don't really think the 10m band covers 25 to 29 Mhz........

Just my useless bit of advice...

Martin, VK2UMJ

So, in other words you're not looking for independent opinions at all (as
per you original posting) because you've already made up your mind that the
BPL is a valid issue and anyone who disagrees with you is a simp. Sorry
Zoran, some people wont throw their hard earned money at an issue just
because you say they should.....

My god, do I actually have to explain this: The Amateur portion of the HF
spectrum is not even 1/6 of the total spectrum. The remainder is controlled
by COMMERCIAL and GOVERNMENT interests that have a hell of a lot more to
lose with BPL's than amateurs ever will. Do actually believe that the ARRL
is going to be the sole group that will rescue the bands from these evil
power companies? Get real Zoran.

If you cant take someone disagreeing with you, try arguing in front of a
mirror.

980. 'Gluing' a broken glass antenna insulator.

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-11 12:18:41 UTC
From: Terry <tsanford@nf.sympatico.ca>
Message-ID: <3F0EAB21.93BBA55D@nf.sympatico.ca>
Source record: 112824

May I insert a practical subject into this news group which frequently discusses SWRs, the speed of electromagnetic propagation and other exotica?
Ever see those adverts where a hefty guy wearing construction Safety Helmet is hanging from one little spot of 'Krazy Glue' from a steel beam?
Last winter I broke a very nice 8 inch (straight glass not an egg shell) insulator into two almost equal pieces. :-(
A 'clean' break in the ribbed section, no lost pieces or chips of glass, the broken two pieces mated perfectly.
So a couple of days ago I 'glued' it with Crazy Glue; one of those cyano-cryolate (sp?); or whatever the proper name is!. Used a generous but not too overflowing amount.
At house temp. it 'seems' to have made a very strong join. And, holding it, so almost, did my fingers when the vapour from the glue seemed to flow away from the join and collect on them! However I've escaped.
Whether I will use it again I'm not sure; probably can't depend on it.
But I thought I might set up a test jig; by hanging from it a plywood platform a few inches above the ground and loading that with concrete blocks/bricks etc.
Any ideas comments what the 'strength' of an unbroken one would be. That is to say what would be a 'normal loading for an insulator of this type. I've seen pictures of wire antennas with incredible loads of, say, ice, on them. And often something will break; but those glass insulators look incredibly strong, unless you drop one as I did.
Regards. Terry.
A few miles from where, in 1901, Marconi received the first Transatlantic wireless telegraph signal.

Cyanoacrylates (crazy glue) are near worthless in a humid and/or UV
environment- guaranteed to fail.

The anaerobic cements by Loctite create a bond stronger than the glass.
Pick up some rear view mirror cement with its primer.

Terry -

I would recommend finding a glass blower (either artistic or commercial)
I may be possible to "reheat" both sections - while still retaining their
shape -
and splice the pieces together in a "plastic state"

Last time I flew to Seattle aboard a 757 I stuck my GPS up to the window and
read out the aircraft speed....526MPH.
Seems like they could use a more upscale comm system aboard planes when such
technology is that common.

Keith wrote:
"Those 0 volts and currents can be measured."

The phase of the incident wave at a distance from the generator is the phase that existed at the generator at an earlier time proportional to distance.

Take a point on the signal traveling on a transmission line which is reflected back toward the generator. It encounters the later generated signal traveling toward the reflection point.

Suppose the reflection is from an open circuit. At the open, incident and reflected waves have the same amplitude and phase. Their voltages add arithmetically. Open-circuit reaction reverses the phase of the reflected current, so incident and reflected currents add to zero.

Back from the reflection, phase of the incident wave advances with distance. We see a signal which was generated more recently the farther back toward the generator we look.

Back from the reflection, phase of the reflected wave lags with distance. We see a signal which was generated farther back in time the farther back toward the generator we look.

At those fixed points on the transmission line where the incident and reflected voltages are exactly out-of-phase, they add to zero.

At those fixed points on the transmission line where the incident and reflected voltages are exactly in-phase, they add to a double of the incident voltage.

The forward (incident) and reflected waves retain their distinctions. But it takes a directional coupler to separate them. The pattern of standing waves is manifested by the sum of the forward and reflected waves.

The forward wave consists of a voltage everywhere associated with a current equal to that voltage over Zo.

The nature of the reflected wave is the same, except it travels in the opposite direction.

Best regards, Richard Harrison, KB5WZI

>technology is that common.

Hi Dick,

It's a matter of economics and regulation more than design, but also
about design.

Electronic gear in the air must meet stringent considerations. These
are based on the simple fact of weight and power consumed. There is a
heat budget to meet, there is a power budget to meet, and there is a
physical volume budget to meet. Equipment must be designed to
co-exist with other equipment (they share the same heat vent, thus the
heat budget). There is also legacy systems to consider and to
interface to. The flight controllers had or have been using tube
equipment (no, not just their screens, some computers).

Much of this is probably already anticipated by state of the art
designs (except for the packaging). Heat and power issues are by and
large far less imposing than older stuff, but packaging still must
conform to other equipment that has no "modern" replacement.

Then back to the economics and regulation. ARINC places stringent
requirements that are by and large stringent in the top loading of
engineering time. That is, it takes a cadre of support personnel to
research and cross-correlate all the various issues demanded to find
its way into a product. When I designed the flight recorder, it was
to MIL-SPEC 883B which is no regulatory slouch. How much do you think
your HF rig would cost against such a standard? $30K would be a good
place to start. Then there is the retro-fit cost to meet the new
system. Abandoning HF for satellite means air and ground systems must
change to follow the trend (it is only a trend after-all) and this ups
the ante such that a large cadre of support people must be
co-ordinated to follow to a long-term schedule of mods and upgrades
(the schedule, in turn, having taken a couple of years to fashion).
Even changing the antenna type to follow the migration from HF to SHF

impacts the air frame and issues of flight safety. This may seem absurd on the basis of civil aviation which can opt into some gear, but commercial aviation must be done across the board.

988. Tuner detunes antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-11 15:37:57 UTC
From: David Cook <nospam.davepc4@comcast.net>
Message-ID: <pRAPa.33186$OZ2.5556@rwcrnsc54>
Source record: 112832

I recently bought an MFJ-986 tuner and have been using it will good results on a balanced feed antenna, but I just found an odd behavior. I have a 40 and 20 meter dipole that I've used for several years, and 20 meter elements are tuned to 14.125 which gives me a decent SWR on CW and the low end of SSB. I thought I'd hook it to the tuner so I could use the top end of 20 meters and tune the off-resonance SWR down. I found that when I hooked the antenna to the tuner and fed it through the Coax1 Direct, the 1:1 SWR point shifted down about 13.950! I took the tuner out of the circuit and it again tunes at the normal frequency. So I tried it on the Coax 2 connector and found that that one shifted the 1:1 SWR frequency down about 14.050. I called MFJ technical support and they, of course, had no clue. I also fiddled with the tuning knobs, thinking that there might be some interaction inside the box even though the coax was in the direct connect mode, but no interaction found. The 40 meter dipole seems stable, as far as the resonance shifting goes, but I haven't done much testing with it yet. Has anyone seen/heard of anything like this with the MFJ-986 or any similar tuner?

Thanks and 73,
-- Dave, WA0TTN

Not to disagree with your point Paul, but the part that makes me uneasy is the
fact that government may wind up with little or no choice because of the
big $$$$$ politicos who seem to be able to buy their way into most anything
given the right connections to the right....well, you get the point.

But the ARRL sure won't be able to stymie that fact, either, with or without
our
piddling amateur contributions. Only knowledgable, responsiple people in the
right places -with the intestinal fortitude to hang tough and fight the $$$$
flow-
will be able to head off this impending HF disaster. I have no idea if such
individuals in such places even exist today.

>a generous but not too overflowing amount.

Two problems arise. One is in the amount of handling these pieces met with your examination. Handling being literal to fingers touching what they should not. The oils in skin could easily create a poor bond (regardless of cement chosen). Two is the amount of cement used. You clearly used TOO MUCH.

>At house temp. it 'seems' to have made a very strong join. And,
>holding it, so almost, did my fingers when the vapour from the
>glue seemed to flow away from the join and collect on them!

This "house temp" description reveals the third point of failure. Cement joins invariably fail due to differences in the coefficient of thermal expansion between the cement and the material(s) being cemented. For glass, the variation of outdoor temperature could easily see the materials pop apart sitting on a picnic table, much less in service.

>Regards. Terry.

Obviously, the load determines the boundary conditions and so it is not
irrelevant. You said that it was, and that's not correct. The load
impedance is what determines the reflectivity. Go ahead and disagree.

> > :-) Yes, very technical. If a math question was posed, I must have
> > missed it.

> What is the superposed sum of the
> two above waves?

Zero.

> What happens to the intrinsic energy pre-
> existing in those waves before they cancel each other?

The answer the intrinsic energy in the waves where the waves exist is stored
in the transmission line, and nothing happens to energy where waves don't
exist. The waves in question don't convey energy from the source to the
load - obviously because they don't propagate from the source to the load.
It ain't rocket science - as you're so fond of saying.

The rate of flow of energy "in" those two waves is not 100 Joules per
second.

> We
> already know that the energy in those two waves joins the forward-
> traveling power wave toward the load.

The energy does travel forward, but not by way of those two waves.

I doubt that the MFJ-986 maintains a 50 ohm Z0 through the device. What
you have probably done is introduce a short section of "transmission line"
that doesn't have a Z0 of 50 ohms and thus detuned your system.

I vary the length of my transmission line as a tuning method. You apparently
varied the length of your transmission line as a detuning method. :-)

Hi Paul,

Given the poor service rendered by the present administration across the board, it takes very little attention to recent FCC events to observe their wholesale indifference to the consequences of their own brand of one-answer-fits-all.

To expect that the other 5/6'ths of those affected will rescue this mis-step is dreaming in technicolor and surround sound. Those who might be affected will simply exercise their right to veto local implementation. Follow the money, there are one or two principals involved and their legislation and regulation has been paid for. The sad fact of the matter is that the current administration employs the balkanization of issues so that no single community has clout against the indifferent neighborhood. The FCC has attempted to consolidate the commercial market through the abandonment of serving community needs. They entirely ignored every comment that rejected this path; the people had to go to Congress to reverse this attitude. Those same aggrieved are wholly unaware of this new plight, and lacking their motivation, it will be a tougher hill for us to climb. I saw little discussion in this regard of consolidation, even though we watch the FCC closely which is to say we were just as indifferent, as a community, to this plight of community service. The simple fact of it is that our ox is being gored (we are not all that concerned about public service as we are about having fun). To put it bluntly, your neighbor will simply shrug off your problem and suggest you go to Radio Shack for one of those filter thingies - you may note the hint of an ironic smile offered.

For those who have NOT read the NOI, the FCC has carefully couched this BPL in the jingo of Homeland Security (sic) and describes this expressly as part of the solution of "the last mile problem" something I have already described in past posts.

Getting real means climbing out of the grave already dug before they throw in the dirt.

there are two possible effects that could do this:
1. the 'change the coax length to fix the swr' effect. where adding or
removing a length of coax changes the impedance seen at the swr meter. some
meters seem sensitive to the impedance itself and will indicate a different
swr even though it really hasn't changed. try adding just a short piece of
coax in place of the tuner to see if this is causing your problem.
2. a poorly constructed switch can act as an 'impedance bump'... that is, if
the wires are too long or badly routed in the box they can act like a length
of odd impedance feedline that can transform the input impedance to
something else... usually this is a relatively small change as the lengths
of the wires are fairly short, but it is more obvious on higher frequencies
where the wire length is a longer fraction of a wavelength. i don't know
the construction of the mfj box, but this effect is worst when bare wire is
used to connect the in/out connectors to the switch, the better way (but
harder to construct and more expensive) is to use short pieces of coax to
connect them.

That was the definition of a traveling wave in a Z0 environment, Richard,
and opens and shorts are not a Z0 environment. Can you give an example of
a virtual short and explain how it develops?

I probably should have used the word "redundant" instead of "irrelevant".
If the reflected power (irradiance) in a Z0-matched system is a given,
then the value of the load is redundant information and is NOT needed
for a solution.

Of course not because they are destroyed at the cancellation point. But
the energy in the canceled waves is indeed conveyed to the load.

>>The rate of flow of energy has to be 100 joules/sec since the energy
>>in those two waves cannot stand still and cannot be destroyed.
>
> The rate of flow of energy "in" those two waves is not 100 Joules per
> second.

Of course it is. We know that 50W of reflected power from a mismatched
load has not been re-reflected and tried to continue to flow toward the
source. We know it never gets past the impedance discontinuity. There's
only one thing that can stop a wave in its tracks without dissipation of
energy. That's another wave traveling in the same direction with equal
amplitude and opposite phase as explained on the Melles-Griot web page.
We are therefore forced to deduce that the other wave exists and indeed
it is predicted by Pfwd(|rho|^2) and the s-parameter term, s11*a1. It
doesn't last very long because it is instantaneously canceled as it
is reflected but we know it has to exist and indeed Pfwd1(|rho|^2)
equals 50W, the exact amount of energy we need to accomplish the
wave cancellation process.

> The energy does travel forward, but not by way of those two waves.

If it doesn't come from the two canceled waves, where does it come from?
Besides the two canceled waves, only Pfwd1(1-|rho|^2) and Pref2(|rho|^2)
exist and there is not enough energy in those two other wave components
to account for the magnitude of Pfwd2. Hecht, in _Optics_ says the
constructive interference energy (flowing toward the load) comes from
the destructive interference event (toward the source). If the canceled
waves contain no energy then there is no destructive interference energy -
without which constructive interference is not possible.

The real issue for security is the deliberately contrived attack on the services. Who in the devil wants to risk all the network to terroristic threat from a purposeful intervention into the service. As I pointed out in my personal reply, the purpose of the service is really a point to point data link through a transmission line. To me it is bizzare that anyone would contrive to perform a service needing confidentiality on a transmission line technique that is wide open to disaster.

Tnx for the treatise, Rich, it clears up a few details that were hanging out there.

Clearly the revolution in technology is dependent on *other* factors more than on
the state of the art itself .
Which shouldn't, but as so often it happens, brings us back to
to the problem of "where do we go from here when the map is so ill defined?"

I can't help it, I keep being diverted back to the basics...all it takes for two
real radio operators to communicate is a basic radio transcieving system with very
minimal or even maybe no external support, and the skill to send and receive
radiotelegraphy....
Shucks, many of us recall when they used that system on aircraft!

Dick

Hi Mike,

You didn't go far enough. The leakage is prima facia evidence of
security loss. The government is the poorest employer of standard
civil encryption services (government meaning those various agencies
that are not affiliated with black box funding).

What was it - a couple of months back some (friendly ruski?) diplomat
sat in his car outside of a government office downloading their
activity with his snooper attachment?

Hi Dick,

One need only look at the defunct 500KHz emergency radio operation to observe that two radio operators was abandoned long ago. And it was "modern" technology in the form of a signature tone that moved it the first step away. And that was after the rules were relaxed (or put in place originally) to require 15 minutes monitoring of each hour.

In less than 100 years we went from spark gap to satellite technology from the Titanic to flight 800 - and neither of those two fared very well for it. In the millennium before, it was semaphore and smoke signals.

Clearly technology is taken up quite quickly by comparison. When I was in DC last year this time, my girlfriend was adjusting the rear view mirror and engaged the OnStar system by mistake (the buttons being located on the mount). Two decades before the best you had was CB, a decade before it was disposable cellular phones.

Hi Mikael,

FM? Has CB changed that much or are you using non type-accepted gear?

The mag-mount could be a problem. One way to test it is to add an
extender cable (using barrel connectors and another 5 or 10 feet of
coax) and see if that changes anything. If so, you have a common mode
issue. You can ignore it as a problem if you simply select the right
length of extension that pulls the SWR down (and never change anything
else).

All this discussion over the insipid subject of flat lines?

A virtual short appears in a line with 100% reflection. The virtual short appears where the sum of incident and reflected waves produces a concurrence of zero volts and maximum current, just as in a true short. The line has zero loss to enable good repetitions of an actual short or open.

You're making it sound as though the energy gets to the load by some
means other than waves. But it's certainly true the amount of energy
that would have been reflected thus preventing it from reaching the
load, was not reflected and was not prevented from reaching the load.
Seems pretty obvious.

> >>The rate of flow of energy has to be 100 joules/sec since the energy

> Of course it is.

There is no flow of energy from source to load via those waves, hence
the waves do not represent a _flow_ of energy.

> We know that 50W of reflected power from a mismatched

That's your story, and you're sticking with it. I know. ;-)

> > The energy does travel forward, but not by way of those two waves.

> If it doesn't come from the two canceled waves, where does it come from?

Like we haven't been through this already? The superpostion of V1 and V2 accounts for all the energy that moves from source to load. But I agree that the affects of V3 and V4 can't be ignored. V3 dimishes the amplitude of the forward moving wave, and V4 effectively dimishes the amount of V2 that reflects back from the 1st boundary. But saying that energy flows along all these paths obviously causes problems for your analysis - namely the destruction of energy paradox, and the reversal of energy flow without reflection, and now apparently, without waves.

In the earlier example, the destructive interference occurs in the
direction of the source. The constructive interference occurs in
the direction of the load.

So what do you think generates the destructive interference energy?
What is the origin of the destructive interference energy that feeds
the constructive interference event? Exactly what wave components are
involved in the generation of the destructive interference energy?

In other words, how does the reflected power Poynting vector get
turned around at the Z0-match impedance discontinuity?

Dave; I'm not a ham but my comment could be; "And in the best tradition of amateur (radio) some hams will find an ingenious way/s to continue the original purpose an interest in communicating and technology". Although it might have to be a bird's feather dipped in some dark liquid substance to inscribe on something called papyrus or parchment or .... ? Right? However it does sound serious.

An example of such ingenuity.
I recall a magazine article, about 50 years ago, about a UK amateur who received the 200 kilohertz (well it was kilocycles then!) BBC programme signal. Filtered out all the modulation and used it as a rock stable input to a heterodyne VFO.
He allowed the 'Variable' portion of his VFO to run continuously, unkeyed.
But he 'keyed' the 200 Khz, or a harmonic of it, plus or minus the variable frequency inside the VFO etc., I forget the exact details, as drive input to his transmitter/PA.
Very stable 'VFO' when your frequency source was the main Long Wave BBC transmitter of that time; and he wasn't 'stealing' anything; just receiving the 200 khz. signal like anyone else!
Good luck to all. Gotta read up some more on this BPL thread.

Even as a non-amateur my opinion is that regulatory authorities in all countries have already all fallen down on the job. Pollution (RFI) from day to day devices such as lamp dimmers, microwave ovens, even shavers and food mixers is rife and uncontrolled. So we'll never know that some unfortunate soul died because an ambulance could not communicate when someone, maybe myself, decided at that critical moment to make some a snack using in my 'electronically' timed; toaster. Or something equally frivolous?

Terry.

PS. Again off a bit OT. But talking about interference to radio antennae and radio frequencies, HF et al! I recall meeting an electrical power engineer who was then pushing the idea of a single wire plus ground/earth power system. His idea, since at that time and now, many communities here are adjacent to the sea, was to use a cheaper 'single wire' transmission system and the Atlantic Ocean as the other conductor!
Some 'fried' fish and uncomfortable sea mammals I reckon?
But do they not use such a single wire/ground system, occasionally in some remoter parts of Australia? Maybe someone could comment on the potential (pun intended!) for interference with radio transmission/reception, down under?

For low-power work with a 75-ohm system, I've hacked a balun by making a length of twisted-pair that's close to 75 ohms, connecting that to the driven element on one end, wrapping about three turns of it through a small ferrite core, and connecting the other end to the coax. Then I put another couple of ferrite toroids over the outside of the coax, one where the twisted-pair connects and another about a quarter wave down from there. It's a bit tough to make a 50-ohm twisted pair, but it might be reasonable to make a 50-ohm twisted quad, where the wires opposite each other are connected together. But what I was doing I wanted to be broadband, and if I was doing it at a single frequency, I'd look at making a "bazooka" balun, I think, using half-centimeter diameter coax centered inside a quarter wave length of copper or aluminum pipe about one and a half or two cm inside diameter, shorted to the coax outer at the end away from the antenna. You can use a couple of "donuts" cut out of foam packing material (styrofoam) to keep the coax more or less centered in the pipe, but don't use too much insulation because it will change the electrical length. -- There are several other balun structures that could work, too. Maybe others will post things that have worked for them.

Cheers,
Tom

Here's a quote from Born and Wolfe, pg. 48, talking about waves
encountering the interface between dense and less dense media:

"Although there is a field in the second medium, it is easy to see that
no energy flows across the boundary. More precisely it will be shown
that, although the components of the Poynting vector in the direction
normal to the boundary is in general finite, its time average vanishes;
this implies that the energy flows to and fro, but that there is no
lasting flow into the second medium."

> Please reference the cross-posting from sci.physics.electromag. Somebody
> predicted that those guys would tear me apart. On the contrary, they
> tend to agree with me.

I tended to agree with what you said there too. You can be very
agreeable when you want to be. :-)

I notice you didn't mention anything about photons dematerializing and
rematerializing over there. Give that one a try. :-)

> Those reflected waves not only destructively interfere, they are
> destroyed so they MUST give up any intrinsic energy in the waves.
> Nothing else is possible.

If you mean they give up their energy to the two waves traveling in the
other direction, then I agree.

> Can I have a hit
> off whatever you are smokin'? :-)

I've got a pack of Camel lights out in the car. You can have 'em.

> > That would only be true if

> > When we realize it's not, there's nothing left to account for Cecil.

> If reflected energy from a mismatched load is not traveling in the
> reverse direction, pray tell what direction is it traveling in?

P2 is energy that had been traveling in the reflected direction and was re-reflected. That's it. Good thing too, because any more than P2 and P1 and you'd have a perpetual motion machine! :-)

> I
> can see you haven't referenced the reflected power flow vector.

I've seen you reference it, but I have seen you define one - or write it out mathematically.

> > There's no conservation of energy problem to solve.

> There certainly is in your scenario. The reflected energy doesn't ever
> change directions but it somehow joins the forward wave anyway. Can
> you spell B-A-F-F-L-E-G-A-B?

You wrote the bafflegab - whatever that is. I certainly never said reflected energy joins the forward energy. That's your invention.

Jim Kelley wrote:
> You're making it sound as though the energy gets to the load by some
> means other than waves.

No, I'm not. The energy in the canceled waves reverses direction and
joins the forward wave. That's what I said over on sci.physics.electromag
and those guys are amazed that anyone would disagree with that assertion.

>> In other words, the disappearance of two waves during a wave cancellation event
>> can result in reflected energy coherent with those two canceled waves. I don't
>> find that in the literature anywhere. Do you know of a reference?

The reply was:
> I'm curious as to what kind of objections people had. It all makes perfect sense to me.

So the disappearance of two waves during a wave cancellation event and
a subsequent energy reflection makes perfect sense to real physicists.
Not one person on that newsgroup objected to my assertion.

> There is no flow of energy from source to load via those waves, ...

Of course there is. All energy comes from the source. Therefore, the
energy in the reflected power Poynting vector originates from the source
and is reflected by the load. ERGO, that energy has flowed from the
source to the load. *ALL* energy incident upon the load comes from the
source, even the energy rejected by the load as reflected energy. The
above statement is simply a steady-state shortcut mantra that bears no
resemblance to reality.

> That's your story, and you're sticking with it. I know. ;-)

You have not refuted it. Until you provide an iota of proof to
the contrary, I'll be sticking with it. Incidentally, your mantras
are not proof. Try uttering your mantras on sci.physics.electromag
and see what happens.

> Like we haven't been through this already? The superpostion of V1 and
> V2 accounts for all the energy that moves from source to load.

We've been through all this before. There is not enough energy in
|V1|^2/Z02 and |V2|^2/Z02 to support the constructive interference
between those two waves. Therefore, an equal magnitude of destructive
interference must be occurring somewhere else - according to Hecht.
Therefore, the destructive interference energy is generated by the
wave cancellation event between the two rearward-traveling reflected
waves just as described on the Melles-Griot web page and agreed
to by experts over on sci.physics.electromag.

How about you reply to my latest posting on sci.physics.electromag
so we can obtain opinions from some real experts? I predict our
differences would be settled in a matter of days on that newsgroup.

Keith wrote:
"So how does energy flow through a point in the circuit where the voltage or current is always 0?"

The "0" is the sum of two voltages produced by adding together equal and opposite voltages in two waves which are passing through each other with no effect on each other.

Conductors producing the volts and amps from the waves they carry are actually "bucket brigades". Distributed inductance and capacitance pass along charges in a travel direction, or in both directions. There is no problem as charges moving in opposite directions swell and shrink occupancy at certain spots on the line. They don`t overflow, and charges moving in each direction, like Ole Man River, they "jes keep movin` along".

Best regards, Richard Harrison, KB5WZI

1030. lining up microwave antenna's

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-11 19:35:16 UTC
From: hees34@zonnet.nl
Message-ID: <MPG.19792fdd6dac8fb989683@news.planet.nl>
Source record: 112774

Maybe somebody can shed some light on the following matter:

Recently I have installed an 18 GHz Microwave link, consisting of NEC-Pasolink gear and Andrews Microwave Dishes.
Because it was a first for me, I had thought over the process of lining up the dishes. I had heard of and read about the side-lobe vs the main-lobe.
So I figured out the my coworker on the other end of the link should move his dish and I would tell him the reading on my voltmeter. The higher the better and at the peak reading he would fix the dish. Then I would do the same on my end. And then his end a second time and then my end a second time
We would repeat this procedure for the vertical line-up as well.
I had calculated an expected attenuation which could be converted in a voltage reading.

Assume the reading should say 3,5 V. Well I never got anything better than 2.8 / 2.9 volt.

COnsequently I asked NEC for advice and they said that 'you should line up you own end using the voltmeter, and not the opposite end'. With this advice we repeated everything and reached the expected reading of 3.5 volt. The 2.8 volt was a sidelobe of the antenna-beam

What I don't understand is that when I rotate my dish (either horizontally or vertically) I can go from sidelobe to mainlobe to sidelobe. I don't move the dish further left or right, I only rotate it around a vertical or horizontal axis. When I would move the dish further left or right or up or down, than I can visualize going from lobe to lobe. Not by rotating the dish
That is why I used the opposite end to move the beam.

Anybody can explain where I go wrong

Regards, Ad

This is just another one of your *NET* energy statements. We are NOT discussing NET steady-state energy. We are discussing the underlying energy components. I have said that dozens of times. I do NOT choose to discuss NET energy. If you want to discuss NET energy feel free to find someone else with which to discuss that boring subject.

> I notice you didn't mention anything about photons dematerializing and
> rematerializing over there. Give that one a try. :-)

I did, and no one objected. But we don't need quantum physics to explain HF RF waves.

> If you mean they give up their energy to the two waves traveling in the
> other direction, then I agree.

I'm glad you have changed your mind about that one. Upon what technical point do we still disagree? If the rearward-traveling waves give up their energy to the two waves traveling in the forward direction, the energy has changed direction, by definition.

>>If reflected energy from a mismatched load is not traveling in the
>>reverse direction, pray tell what direction is it traveling in?
>
> P2 is energy that had been traveling in the reflected direction and was
> re-reflected. That's it. Good thing too, because any more than P2 and
> P1 and you'd have a perpetual motion machine! :-)

There is not enough energy in P1 and P2 to support Pfwd2. Constructive interference energy must be added into Pfwd2. According to Hecht, that constructive interference energy can only originate from destructive interference. There is no destructive interference energy source except from the wave cancellation between two rearward-traveling reflected waves.

> I certainly never said reflected energy joins the forward energy.

Here's what you said earlier in this very posting.

> If you mean they give up their energy to the two waves traveling in the
> other direction, then I agree.

"They", above, are reflected waves. The two waves traveling in the other direction are forward waves. So you said the reflected waves give up their energy to the forward waves.

Hi Ad,

Looks like cross-polarization issue. As you rotate, they come into conflict (the polarizations) and then re-emerge from conflict. Actually, it sounds fairly bullet proof with what you got (plenty of signal, the system probably doesn't need more than a volt, as you would measure it).

Source record: 112780

I'm considering installing an inverted V 40 meter dipole under the eaves of my house. There is room for a longer arm on one side than the other.

1) Would I be better off making each arm as long as possible and adding whatever matching circuit is required?

2) Should I make both sides equal to the shorter arm even if this makes the antenna too short to self resonate?

3) Should I make both sides equal in case there is sufficient length to allow the antenna to self resonate.

Sorry for the complexity of the question.

Thanks for any help.

Source record: 112782

If you think 10 dB is insignificant, try to explain why to the person who's proud of his 7 element single band Yagi mounted on a 1.3 wavelength boom, which is how much you need to get 10 dB gain over a dipole. Or the person who just bought a kW amplifier to drive with his 100 watt rig.

I've yet to see an S-meter with units greater than about 6 dB. Less than this is much more typical. The S units on my Icom 730 vary from 1.3 to 4.0 dB, depending on where on the scale you are. A 10 dB signal change will move the meter from S-2 to S-7.

This isn't to say you can't work a whole lot of stations with 10 watts, or a 100 watt rig into a 10% efficient antenna -- or even with one watt. But you will notice a difference when you increase or decrease your power 10 dB.

Roy Lewallen, W7EL

The additional length of coax and the tuner changing the "RESONANCE" of an antenna indicates that the antenna[s] did not have Zo = 50 +/- j0 ohms. Restated, there was a mismatch! The length of transmission line from the antenna[s] to the rig tuned the apparent resonance to 14.125. BTW resonance is NOT indicated at a VSWR of 1:1. Resonance is when the reactance in the ANTENNA IS ZERO.

So, adding extra components in the system changed the apparent VSWR not the antenna resonance.

BTW, I'm currently using a trap vertical as an interim antenna that has measured resonance[s] between 26 to 37 ohms resistive from 10 to 40 meters. That's a VSWR approaching 2:1. A tuner or extra lengths of coax will tune the ANTENNA SYSTEM to an apparent VSWR of 1:1 [but I know better! My VSWR is still ~2:1 and my antenna resonance is still 26 to 37 ohms resistive]. MFJ 259B Antenna Analyzer used for measurements.

#chuckle# Yeah, it's largely a matter of perspective.

>I've yet to see an S-meter with units greater than about 6 dB.

You're right - my recollection was off by a factor of 2:1, dB-wise.
1 S-unit is often held to be 6 dB, twice the voltage, four times the
power. That seems to be one of those Platonic ideals which can only
be approached asymptotically, but never reached in practice.

Yeah, there seems to be a _lot_ of inconsistency and variation between
different manufacturers, different rigs, different sorts of S-meter
scaling circuit, and (I suspect) different portions of the dial on any
given example of any of the above.

That Icom 730 reading sounds as if it's got something close to a
linear calibration rather than a log calibration!

> matching circuit is required?
>
You didn't say what actual dimensions you have available, or whether
the total gets you up to 66' (or so). But it sounds like your shorter side
is less than 33'. No, don't use excessive (for resonance) length, if you
intend to have a resonant monobander.

> 2) Should I make both sides equal to the shorter arm even if this makes
the
> antenna too short to self resonate?

No. If your short side is less than 33', make it as long as you can.
Then trim the long side for lowest SWR at your desired center frequency.
There should be no problem at all with unequal sides, within reason.
In fact, unbalancing the sides physically can sometimes improve the
electrical balance, and/or minimize SWR, if done correctly.
>
> 3) Should I make both sides equal in case there is sufficient length to
allow
> the antenna to self resonate.

That would be the "classical" way to do it; and if you got a good match,
you'd be done.

But if you like fine tuning, try adding a foot to one side, and measure
center freq and SWR. Then put the extra foot over on the other side, and
again measure center freq and SWR. The center freqs should be the same,
or very close. But if one configuration shows lower SWR, that is telling
you that a physical imbalance in that direction will improve your match.

My 40/80 trap dipole works best on 80 when one side is about 3' longer
than the other!

There won't be much practical difference in radiation from the antenna itself among the choices. But it's much more difficult to suppress feedline radiation when the sides have different lengths. Since the feedline is likely to be in close proximity to house wiring and appliances, it's probably a good idea to keep feedline radiation to a minimum. This means using a current balun at the feedpoint, and possibly another a quarter wavelength or so farther down the feedline. People using off-center fed dipoles have reported difficulty in suppressing feedline radiation even with fairly decent baluns, but it should be possible. Of course, if the asymmetry isn't great, there shouldn't be much of a problem. The advantage to making the overall length closer to resonance is a higher feedpoint impedance (which you might be able to get close enough to 50 ohms to obviate matching) and a bit greater bandwidth. The trade between this and the potential difficulty in suppressing feedline radiation is up to you to make.

What I'd probably do is make the dipole symmetrical, match it at the feedpoint with lumped components, and feed it with coax via a current balun at the feedpoint. But that's only one of a number of possible, and about equally workable, solutions.

It's the same factor that kept the Interstate Police HF Radiotelegraph Net in operation into the early 70's even though wireline teletype had fully matured many decades earlier. The cost of dedicated wire lines, monopolized by one AT&T in those days, was just too high to justify. Plus some states and others hired personnel to do "double duty" with both commercial radiotelegraph operators and radidotelephone operators licenses so that they could handle interstate and
interdepartmental Morse messages, operate the voice dispatch centers, and do low echelon radio maintenance as circumstances demanded. Of course it's all gone now.

> > Wanna talk about Luddite methods of communication? How 'bout

In 1972 I worked Bill Leonard, W2SKE, the TV news veteran, on 2 meters simplex when I heard him calling CQ /aeronauticala mobile. He was on a jetliner 30 m inutes out of Dallas at 30K feet headed for New York City, using a rig identical to the one I was using mobile at the time- a Drake TR22. All of a watt and a half on each end. He said he was holding his up to the window of the Boeing 707 (in the days prior to the banning of such operation) Our path didn't last long but we sure had a good noise quiet QSO while it did.
THAT was some pretty simple, inexepensive, unsophisticated but very workable technology. Looks to me that sometimes high-tech can get in the way of getting things done. But it's SACRED, and almost sacreligious to make such a statement.

Actually it's just a quote from an optics book describing, among other things, how a field can cross a boundary without energy necessarily flowing across it. It happens to be the same thing I've been trying to explain to you.

> > I notice you didn't mention anything about photons dematerializing and

I searched the entire thread. Not one mention of photons dematerializing or rematerializing.

> Upon what
> technical point do we still disagree? If the rearward-traveling
> waves give up their energy to the two waves traveling in the
> forward direction, the energy has changed direction, by definition.

Actually you have it backwards. If energy had been reflected, the forward waves would have given up their energy to the reflected waves. The reflected waves only give up their energy in a sense by not taking it in the first place.

> There is not enough energy in P1 and P2 to support Pfwd2. Constructive
> interference energy must be added into Pfwd2.

P1 and P2 are the only terms in the equation, Cecil. Obviously they have enough energy to produce the correct answer. But I know what you are getting at, Cecil, and it is interesting. But the example Joseph Legris gave you (the same one I described previously) should illustrate for you the problem with what you are saying. It's apparent from that example that energy from the lasers goes directly to the constructive interference side without having to come from somewhere else (other than the source). And it's also true that that only occurs when destructive

interference is also occurring elsewhere.

> According to Hecht, that
> constructive interference energy can only originate from destructive
> interference.

What he's saying is that you can't have one without the other.

But nobody cares about your *NET* energy quotations. This thread is
about the energy components underlying the steady-state solution.
What is it about that statement that you don't understand? If you
want to discuss net energy, please start another thread.

> I searched the entire thread. Not one mention of photons
> dematerializing or rematerializing.

It was in another thread, Jim.

> Actually you have it backwards. If energy had been reflected, the
> forward waves would have given up their energy to the reflected waves.

The forward wave *DOES* give up (Pfwd*|rho|^2) energy to the reflected wave
at a mismatched load. I'm sorry to pull an argumentum ad populum on you
but everybody on this newsgroup knows that except you.

> The reflected waves only give up their energy in a sense by not taking
> it in the first place.

More Bafflegab. Please research the reflected power Poynting vector from
the previously provided reference of Ramo and Whinnery and get back to
us.

> P1 and P2 are the only terms in the equation, Cecil.

Which leads you to believe that P1+P2 > P1+P2? What is it about destructive
interference energy feeding energy to the constructive interference event
that you do not understand?

Assume Wave(1) is associated with P1 and Wave(2) is associated with P2.

P1 + P2 + 2*Sqrt(P1*P2) is the proper equation when Wave(1) and Wave(2)
are in zero phase. On the other side of the impedance discontinuity we
have a similar equation: P3 + P4 - 2*Sqrt(P3*P4). Agree so far?

Pref1 = P3 + P4 - 2*Sqrt(P3*P4) = zero reflected power toward the source.

So P3 + P4 = 2*Sqrt(P3*P4) = 100% destructive interference during wave
cancellation, i.e. Wave(3) and Wave(4) are destroyed. The destructive
interference equals the total of P3+P4 *because* those waves were
destroyed. Wave(3) and Wave(4) give up their combined energy components

as destructive interference energy.

Hecht tells us that the magnitude of the destructive interference must equal the magnitude of the constructive interference. Guess what? He is right! |2*Sqrt(P3*P4)| does indeed equal |2*Sqrt(P1*P2)| and we can simply say that according to Hecht, |2*Sqrt(P1*P2)| comes from |2*Sqrt(P3*P4)|. The destructive interference event supplies the power for the constructive interference event. I'm getting tired of typing the following quote from _Optics_, by Hecht:

"The principle of Conservation of Energy makes it clear (to everyone except Jim) that if there is constructive interference at one point, the 'extra' energy at that location must have come from ... destructive interference somewhere else." I don't know how Hecht could have said it any clearer. The constructive interference energy is supplied from the destructive interference event.

So the valid equation becomes P1+P2+2*Sqrt(P3*P4) = P1+P2+P3+P4, i.e. all the power in the entire Z0-matched system winds up flowing toward the load but we already knew that. How you can argue with that fact is simply unbelievable.

> What he's saying is that you can't have one without the other.

Yes, and the destructive interference event *supplies* energy to the constructive interference event. It certainly cannot be vice versa as you are attempting to imply. Hecht was very careful to say that constructive interference requires a source of energy from a destructive interference event. See above quote.

About this "reflected power Poynting vector" -- first read this quote from King, Mimno, and Wing's _Transmission Lines, Antennas, and Waveguides_. It begins at p. 220 of the Dover paperback edition:

"Note that, whereas the real part of the _integral_ of the normal component of the complex Poynting vector S over the surface of a great sphere (or any other completely closed surface) correctly and uniquely gives the average power lost by the moving charges on one side and gained by the moving charges on the other side of the surface, the conclusion cannot be drawn that the real part of the complex Poynting vector at some point on the surface is itself a measure of the _fraction_ of the toal power that is transferred across a unit area at that point. There is nothing in the mathematical analysis to justify such a conclusion, and experimental verification is available only for the _total_ power as measured by the complete integral. In fact, it is analytically possible with equal correctness to define a veriety of energy-flow functions that are entirely different from the Poynting vector. Each of these functions gives a _different_ value to the power transferred across a particular unit area, but they all give exactly the same total power when integrated over the same closed surface. It is the integral of the normal component of the Poynting vector over a closed surface that is important, not the Poynting vector itself."

So where do you draw the required surface over which to integrate the Poynting vector and thus obtain the "reflected power"?

Would you please give a simple example, with numbers, showing how this quantity is calculated?

Roy Lewallen, W7EL

Only because of economic reasons. The "technology" worked just fine
but the shipping companies figured out a way to save $100,000 per
vessel per year, which is really peanuts compared to the cost of
operating a modern cargo vessel ($5000 per day to tie up at the
dock), by getting rid of the Radio Officer, and that was only in the
last 5 or so years.

>And it was
>"modern" technology in the form of a signature tone that moved it the
>first step away.

Do you mean "auto alarm" sequence? That wasn't a tone. It was
twelve (or more) 4-second dashes (3.8 sec. to 4.2 sec. by _my_
stopwatch) with one second silence between them. I inspected and
tested an awful lot of auto-alarm generators and receivers during
ship radio safety inspections over a period of 30+ years until the
GMDSS system came in and those inspections were privatized.

Standing watch by auto-alarm receiver was permitted only on cargo
vessels which carried one operator who was required to be on duty
eight hours a day. The auto-alarm watch could be used when the
operator was off-duty or on a break.

The four-second-dash auto-alarm signal was sent to alert other
vessels and shore stations that a Distress Call (with the famous
SOS) was following. On shipboard, if watch was being kept by
auto-alarm receiver, reception of the auto-alarm signal would
trigger a loud bell on the bridge, in the radio operator's cabin,
and in the radio room. One could not miss that activation !

The radiotelephone auto-alarm signal was a two-tone signal to
actuate a muted 2182 receiver on the bridge. It was supplanted by a
watch receiver on 2187.5 kHz in a Digital Selective Call system.

>And that was after the rules were relaxed (or put in
>place originally) to require 15 minutes monitoring of each hour.

Not quite.

The original pre-WW-II requirement was two "silent periods" of three minutes each, starting fifteen minutes after the hour and 45 minutes after the hour. During those periods, as well as when not actually sending and receiving traffic on another frequency, the operator on duty was obliged to monitor 500 kHz for distress traffic. After WW-II, a similar requirement was added for radiotelephone distress traffic on 2182 kHz, with the silent periods of three minutes each starting on the hour and half-hour.

Each radio room was required to be equipped with a special clock having the silent periods marked - a red wedge for the telegraphy silent periods and a green wedge for the radiotelephone silent periods, as well as red markings around the periphery of the dial for the four-second auto-alarm dashes.

Such a clock, made by Chelsea in six-inch size in a heavy brass case with an 8-day precision windup movement, would fetch about $800 now if one could be found, but a replica 10 inch diameter wall clock with a quartz movement (and all the right markings) is available on the internet for $15, believe it or not. I have one on the wall of my comm room / ham shack and it's just as advertised at:

<http://www.cafeshops.com/amradio,amradio2,amradio3.4044580>

(I'm not connected with them in any way.)

>In the millennium before, it was semaphore and smoke signals.

In 1965, in celebration of its centenary, the ITU published a wonderful "coffee table" book entitled "From Semaphore to Satellite" which covered the events and technology of its first 100 years including some very interesting pictures. I don't know if it is still available, but I was able to pick up an original edition when I was in Geneva on ITU business in 1967.

>Two decades before the best you had was CB,

Nonsense. I had a 2-meter transceiver in my car in 1958, which worked through a repeater in Los Angeles, crystal controlled AM, of course. Many of my friends who were hams did, too. By the time that the "CB" craze hit, we had 2-meter crystal-controlled FM rigs. My first mobile dial-the-channel synthesized 2-m transceiver (Icom IC-280) was in 1976 and my first 2-meter mobile transceiver with memory channels, variable offsets, CTCSS tones, and all the bells and whistles was in 1986 (and I was a "late bloomer" on that one) when cell-phones were still lunchbox-size and their coverage was spotty.

At a single boundary, yes. We are discussing the effects of a pair of
boundaries.

> > P1 and P2 are the only terms in the equation, Cecil.

> Which leads you to believe that P1+P2 > P1+P2?

I don't believe that.

There exists no mechanism for them to "give up" their energy in the way
you describe.

> "The principle of Conservation of Energy makes it clear (to everyone except

Unless you're prepared to ask "everyone except Jim" what they think, we can assume this is nothing more than a rhetorical statement that contributes nothing to the discussion.

> So the valid equation becomes P1+P2+2*Sqrt(P3*P4) = P1+P2+P3+P4, i.e.
> all the power in the entire Z0-matched system winds up flowing toward

> is simply unbelievable.

I've never disputed the solutions produce the same number. I disputed the validity of the approach you took to arrive at the equation.

No tuning required on the TA-33. If your into phone use the holes on each element that are for phone (shorter ones). For mainly low end use the longer holes spots.

Make sure the strap goes from the driven element to the cross piece support for the driven element. Basically just follow the instructions. Make sure the spacing is correct and go for it.

Of course it will. Why do nitpicking busy-bodies stir up worries about radiation from feed-lines? It's never wasted.

Feedline radiation may disappear in unknown directions, but, even when a dipole is centre-fed, the radiation pattern in the midst of the usual environmental cluttering uncertainty, and the manner in which the feedline is led away from then antenna, the whole thing is always a matter of guesswork.

As the antenna is non-rotatable it doesn't matter very much what the very uncertain distorted radiation pattern is anyway.

Just erect the antenna in the best possible way you can manage in the limited space available and see what happens. Most likely you will not be disappointed in its performance.

Good DX !

What I did not mention is that is that I live in a condo with antenna restrictions. But I figure if I put the antenna under the eaves of the house, it will be virtually invisible except at the apex where the the feed wires enter the attic. I have purchased a B1-5K balun from Radio Works and plan to use it on the attic side of the wall.

I am now using a Buddipole in the attic and it works, but I am hoping to get better radiation (and less telephone and TV RFI) by using a full length dipole and getting it at least a little further away from attic wiring, heating/AC ducts, etc. Also I am afraid to run more than 100 watts, not only due to RFI concerns, but from a fire safety standpoint as well.

I just bought an Autek antenna analyzer which I think will come in handy. At least with a feed point in the attic, I should be able to make impedance measurements easily.

So I would like to use a Carolina Windom, but my situation will not allow it. We have lots of tall trees in the back yard and I often look at them longingly, but realistically I think I'm just day dreaming, hi. Anyway, thanks for all replies.

Dave,

Can I come back to a point you made earlier? You wrote.....
- Add a choke balun where the coax reaches the tuner (just take 8-10'
of the coax, and wind it into a loop 8-10" in diameter and use
tiewraps to hold it together). This will help maintain balance
between the two sides of the dipole.

There is not enough supplied Coax available to make the choke balun and
still reach my transciever. There are no markings on the cable supplied by
Icom but it looks like they use RG8U. I haven't purchased cable in many
years and seem to remember that insulation and shielding varies by
manufacturer. I'll look for maximum shielding but wonder whether foam
insulation is OK for the choke balun?

Somewhere in the back of my mind I remember seeing something about the cons
of foam insulated coax. Am I getting paranoid?

Myron

Hi Roy,

Nevermind that most who post here that suffer from feed-line radiation
can now rest at ease with their plight knowing that the problem is
their own nitpicking (Punchinello has obviously never kissed a mike
like Cecil - that or his glass of wine insulates/anesthetizes his soft
tissues).

Ever thought of using a tuned loop (very small like a gamma match, or
similar) driving a rain gutter? You might be able to hide the
components behind it under the eaves.

This, in parts of Britain, is called nit-picking (British nits seem to
be unrelated to photometric nits). Anyway, any coupling from feed
line radiation into nearby susceptible wiring can be suppressed with a
current BalUn. Given the proximity of so many opportunities to
distort the field, you are sure to suffer imbalance (the leading
contributor to Common Mode). If these problems arise from the
radiator's field, distance is the best solution.

Hi Ron,

A thin wire with beige coloring could be nearly invisible (the keyword
being "nearly" ... depends on the visual acuity of the antennazis).

Roy Lewallen wrote:
> So where do you draw the required surface over which to integrate the
> Poynting vector and thus obtain the "reflected power"?

As you know, a one-dimensional transmission line is a lot easier to
work with than the 3D space involved with radiation from antennas.
In fact, all we need for a transmission line Poynting vector is
a plane. Since the field area of the coax is constant and known, we
can treat it as a constant normalized value. It allows us to come
up with a simplified version of what you posted. Quoting from,
"Fields and Waves in Communications Electronics", by Ramo, Whinnery,
and Van Duzer: "... we are often most interested in the ratio of power
in the reflected wave to that in the incident wave, and this ratio is
given by ...

Pz-/Pz+ = |rho|^2"

where Pz- is the reflected power Poynting vector, Pz+ is the forward
power Poynting vector, and rho is the reflection coefficient. Pretty
simple stuff that I learned 45 years ago. Again from the same book:

Pz+ = (E+)x(H+) and Pz- = -(E-)x(H-)

If it exists at a single boundary, then it exists.

>>Which leads you to believe that P1+P2 > P1+P2?
>
> I don't believe that.

If you believe that all the power comes from P1 and P2 in the following
equation, then yes, you do believe that.

P1 + P2 + 2*Sqrt(P1*P2) = Pfwd2

Hint: the 2*Sqrt(P1*P2) power does NOT come from P1 and P2. If it did
you would be violating the conservation of energy principle and creating
free energy. That term is the *INTERFERENCE TERM* which is supplied from
the destructive interference going on on the other side of the impedance
discontinuity. Why do you have such a problem with the concept of
conservation of energy?

>>The destructive
>>interference equals the total of P3+P4 *because* those waves were
>>destroyed.
>>Wave(3) and Wave(4) give up their combined energy components
>>as destructive interference energy.
>
> There exists no mechanism for them to "give up" their energy in the way
> you describe.

The mechanism is conservation of energy involving destructive interference
feeding energy to the constructive interference event. The guys over on
sci.physics.electromag can explain it to you.

I used to work in advertising. Don't believe everything you see :-)

Otherwise, try the web sites for the Wireman, Surplus Sales of
Nebraska or whatever -- they got lots of insulators; the Surplus
folks, in particular, have lots of pretty glass jobs.

It might not live up to it's full potential though. "Stunted RF
syndrome" I'd rather have the rf radiated at 40 ft where the antenna
is, rather than the line which ranges from 40 ft down to ground level.
The ground losses of a radiator laying on the ground shouldn't be
ignored. :-) Also, the ground clutter factor. Yes, RF does have many
Superman qualities, such as traveling faster than a speeding bullet,
and being able to travel through most walls at will. But some walls
are metal or even "gasp" lead, and this would prevent the RF from full
exposure to the ether in that direction. But the most important reason
is it whacks out my radios, puters, and other gadgets and causes them
to malfunction in strange and mysterious ways. Also, I don't drink
much wine anymore, so I'm not "medicated" against possible mike burns.

Using my beam at field day, they made 700 and some odd?? 20m CW qso's with it up only 30 ft or so. It'll work and still have the ??? gain over a dipole at that same particular height. In some cases, the low beams will have as good or sometimes even better, medium distance signals than the high beams. But like one said, for real long haul dx at low angles, like 20m at night, the higher the better. You will still work dx though even at 20-25 ft. MK

Mark, Roy,

Of course you would ! So would everybody else.

But iustead of making a federal case out of it, if the question is read again it will be seen to obtain a longer antenna length and something nearer to resonance, Ron is being forced to compromise.

And if there IS a bit of RF inside the house most likely it will be due to the antenna's near field anyway. There's only one way to find out - suck it and see.

Reg.

1073. Check resonance frequency with GDO

Cecil, W5DXP wrote:
"What caused the voltage to go to zero?"

Equal and opposite voltages. Reaction to connecting wires together generates an opposite voltage which adds to zero with the incident voltage. Current doubles at the short.

1/4-wave back from the short, a virtual open circuit appears. Cecil claims this open circuit does not impede current.

1/4-wave short-circuit stubs are used as metallic insulators. They have the characteristics of resonant circuits constructed of a parallel-connected capacitor and coil, a very high impedance at resonance.

From King, Mimno, and Wing, "Transmission Lines, Antennas, and Wave Guides" page 29:

"A short-circuited line, one-quarter wavelength long at the desired output frequency may be connected across the output terminals of a transmitter or across the antenna feeder at any point without placing much load on the transmitter at this fundamental or desired output frequency, since at this frequency such a section has an impedance ideally infinite, actually about 400,000 ohms."

Since I = E/Z, how much current do you think will flow into 400,000 ohms?

King, Mimno, and Wing`s impedance might scale down to only 33,333 ohms on a 50-ohm line, still high, as they may have been considering a 600-ohm line.

All my radar texts say resonant transmission line sections have the same characteristics as resonant lumped circuits and I trust them because the radar circuits using tuned transmission lines to route the signal, work.

Best regards, Richard Harrison, KB5WZI

Forward waves? Being, I suppose, a voltage wave and a current wave, as it is impossible to have two voltage waves or two current waves of identical frequency traveling in the same direction on the same line. Two identical frequency waves, voltage or current, form a resultant and merge. They can`t maintain a separate existence and become inseparable in a single waveform.

Hello,

A while back I saw a program that could have two grid references entered
together with rough antenna heights and power etc. The program give a side
view of the path and terrain. This was used in the UK and a DOS program.
It also calulated the path loss and put a line between the two sites to show
how the signal would be blocked by hills for example.
Anyone know what it is called or where to obtain it from ?

What caused the rearward-traveling current to go to zero at the
same time?

The problem is one of cause and effect. You cannot say the virtual
short causes the voltage and current wave conditions and then say
the voltage and current wave conditions causes the virtual short.

> 1/4-wave back from the short, a virtual open circuit appears. Cecil
> claims this open circuit does not impede current.

If the virtual short causes reflections, why doesn't the virtual open
cause reflections?

> 1/4-wave short-circuit stubs are used as metallic insulators.

That's nice, but we are not discussing physical shorts. We are
discussing virtual shorts.

1079. Re: Conservation of Energy

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-12 10:55:37 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <vgvq9ld82nl9b@corp.supernews.com>
Source record: 112721

It's actually easy to predict the (resistive) impedance seen looking into a shorted quarter wavelength line, or any odd multiple. The impedance is simply the Z0 of the line divided by the loss in nepers. One neper is about 8.7 dB, so the impedance is about 8.7 * Z0 / dB loss.

All else being equal, the impedance gets higher as frequency increases. That's because the length of a quarter wave stub decreases in inverse proportion to frequency, while loss (up to 1 - 10 GHz or so, where conductor loss dominates) increases only as the square root of frequency. So the impedance of a stub increases as the square root of frequency. For example, a quarter wave stub, made from solid polyethylene dielectric coax (VF = 0.66) at 3.5 MHz is about 46 ft. That length of RG-58 has a loss of about 0.3 dB, so the impedance looking into a quarter wave stub of RG-58 at 3.5 MHz is about 1450 ohms. Quite a far cry from the textbook's example of 400 k ohms or Richard's extrapolation to 33 k ohms! An RG-58 stub at 350 MHz, or 100 times the frequency, would have an input impedance of about 14,500 ohms.

A more typical VHF example would be a quarter wave of RG-8 at two meters. It would be about 13.4 inches long and a loss of about 0.03 dB, for an input Z of about 14,500 ohms.

Incidentally, the formula I'm using is actually on the same page of King et al's text as the 400 k ohm value Richard quotes. They say the 400 k value is for "a reasonably low-loss line" -- to get 400 k ohms with a 600 ohm line, the loss would have to be about 0.013 dB.

The input impedance of an open circuited quarter wavelength line or shorted half wavelength line is Z0 times the loss in nepers, or about Z0 * dB loss / 8.7.

I actually ran into a case where the finite resistance of an open stub became a problem, and it illustrates the hazard of blindly following a "rule of thumb" without checking to see under what conditions it's valid. The "Field Day Special" antenna, similar to a ZL special, can be fed at the center of either element. I connected a one wavelength transmission line to the center of each element, and fed one or the other to switch directions, leaving the other line open circuited. When RG-58 was used, the current diverted into the finite resistance of the open stub disturbed the element current enough to very significantly degrade the front/back ratio. The lines were one wavelength at 14 MHz, or about 46 feet. Loss was a seemingly trivial 0.8 dB, but that means that the input impedance was only about 540 ohms! 400,000 or even 33,000 would be an awfully poor estimate! Changing to 300 ohm twinlead solved the problem. (Although 300 ohm twinlead can easily be as lossy as RG-58 when wet, the higher Z0 resulted in an adequately high stub impedance

even when it was wet.)

Hello Dick:

I rec'd the following yesterday as you probably did as well;

SB QST @ ARL $ARLB043
ARLB043 ARRL files comments, studies in Broadband Over Power Line
proceeding

ZCZC AG43
QST de W1AW
ARRL Bulletin 43 ARLB043
From ARRL Headquarters
Newington CT July 10, 2003
To all radio amateurs

SB QST ARL ARLB043
ARLB043 ARRL files comments, studies in Broadband Over Power Line
proceeding

Pointing to a potential for interference to and from Amateur Radio,
the ARRL has called on the FCC to "take no steps" to permit
Broadband over Power Line (BPL). The League's 120-page filing, which
includes several lab studies, was in response to the FCC's BPL
Notice of Inquiry in ET Docket 03-104, published May 23.

Comment: OK, this is fine, however where are these studies posted and who
performed them? Is this similar to the only study the ARRL possesses on
CC&R's that was done in 1988 in Boulder CO (which is the 4th most liberal
place in the US). The League is pouring thousands of dollars into that
particular lobbying effort (CC&R's) and resting their laurels on an inept 15

year old study. When I started investigating the CC&R issue, I found out that the only evidence the ARRL had to persuade Congress (other than throwing $$$ at them) was this pathetic study.

ARRL said the Amateur Service should not be "gored with the double-edged sword of an incompatible service" that will at once cause widespread interference and preclude any future changes in the amateur HF allocations.

Comment: OK, this is still on point but wht does the league need my money?

Citing "diligent and exhaustive research," ARRL concluded that BPL must avoid any and all amateur MF, HF and VHF allocations without exception.

Comment: What "diligent and exhaustive research," ? When someone asks you for $$$, dont they usually give you some stated facts relating to the reasons for the request? This is like reaching into a box of unmarked resistors and assuming that the one you pick is the correct value.

"This interference potential, as a matter of both law and fact, disqualifies access BPL as a potential future competitive broadband delivery system," the ARRL said in its comments.

Comment: CASE CLOSED. Its already a matter of law. No money needed.

League studies show received signal levels of BPL broadband noise at typical amateur stations would be anywhere from 33.7 dB to 65.4 dB higher than typical ambient noise levels in worst-case situations.
NNNN
/EX

Comment: Typical amateur station? 33.7 dB to 65.4 dB from what noise floor? WHERES THE BEEF?

It is always better to have a beam up than to be thinking of how to put it up. If that is the best setup at the present time go for it. Every day that it is not on the roof is missed contacts. There will always be "nay-sayers" to any setup, make the best of what you have and enjoy.

IMO they're just following the standard organizational philosophy, that being

"Get the money while you can, while you have a good reason to request it".

Seems all organizations now operate under this plan and thus they always have
funding
available (provided they can keep from squandering it on unnecessaries) during
times when they don't have a hot-button "issue" to scare contributers with..

> in a single waveform.

Of course they superpose. In the s-parameter equation, b1=s11*a1+s12*a2,
those two reflected waves superpose to b1. In the s-parameter equation,
b2=s21*a1+s22*a2, those two forward waves superpose to b2. They superpose
at the point where they both appear together for the first time.

But the point is that s11*a1 and s12*a2 are flowing in the direction
of the source when they cancel (interfere destructively). s21*a1 and
s22*a2 are flowing in the direction of the load when they interfere
constructively.

I am not aware of any single program which will satisfy your stringent "specification".

From the following website you can obtain several programs something along the lines you are looking for. But there are no grid references. Ground conditions, if entered in a program, are described in terms of types of terrain, or soil resistivity and permittivity.

They are all self-contained DOS programs. Each program can be downloaded in a few seconds and can be run imediately. Computed results are available on an easy-to-use 'What-if?' basis.

GRNDWAV3. Groundwave propagation, field strength, Tx to Rx input from ELF to HF, includes diffraction over the radio horizon, path length up to several thousand kilometres.

DIFFRAC1, DIFRAC2. Propagation predictions, from Tx to Rx, over obstructions such as buildings or mountain edges, and over two successive obstructions.

LINOSITE. Elementary ball-park prediction of line-of-sight propagation for given antenna characteristics.

There may be other programs of interest, such as design and behaviour of transmission lines to better than ordinarily required engineering standards and may be used to check more simple programs. See brief descriptions of program applications on website download page.

Here is the relevant text from that web site.

""PRUNING" ANTENNAS
The unit is shirt-pocket sized so you can use it up the mast. To check a vertical 1/4 wave (for example) disconnect the feeder, and short the antenna with a bit of wire about 5-10cm long. Twist the wire to form a single turn loop and check this loop with the GDO as above. If the ANT is too short the DIP will be higher than the frequency you want."

This is probably not the newgroup I need to be on, but perhaps someone could point me to one better suited for my question.

I want to buy a portable AM radio that will receive a distant station that is close (in frequency) to a nearby station. The radio in my car does this just fine, but not any of the portable radios I've tried. I. The guy at Radio Shack told me I needed a radio with a digital tuner, so I bought one. Didn't work so I took it back. The display was digital; I don't know if anything else was. I had similar results at Circuit City and Best Buy. The clerks at these places appear to be clueless.

Appreciate any help.

Dave

It was written by G4JNT, and it contained a real UK terrain database. It
hasn't been supported for ages, but one of the UK microwavers may still
have a copy.

There are much more accurate VHF/UHF propagation programs around now,
with more detailed UK terrain databases and also better-verified
propagation models, but AFAIK they are all proprietary.

there are two major specifications for a receiver that you should look at.
first is 'sensitivity' this is a measure of how weak of a signal the
receiver can detect. this is usually stated by specifying the signal level
in micro-volts at the antenna terminals needed to produce a signal with a
given signal to noise ratio. as an example, the ft-1000mp in the .5-1.8MHz
range in AM mode needs 16 micro-volts to generate a 10db signal to noise
(s/n) ratio according to its specs.

the other other big one is 'selectivity'. this is a measure of how far away
from the desired frequency the receiver can reject interference from another
station. This is normally specified in kHz away from the center frequency
to reduce the interfering signal by a given number of db. again, for the
ft-1000mp in AM mode it is 4khz for -6db, and 14khz for -60db... so a signal
14 khz from the indicated receiver frequency is reduced by 60 db.

there are some others that are used to classify higher end receivers. one
of those is 'Dynamic Range', this is a measure of the smallest to largest
signal the receiver can handle without adverse effects. usually stated in
db, the ft-1000mp is rated at 108db.

as you found out, a digital display doesn't mean a good receiver. in fact
many 'digital' displays are just cheap frequency counters that hide a plain
old analog receiver behind it. truely digitally tuned radios will normally
have a set of memories that can store frequency and mode information for
instant recall... but they are not always better receivers.

another important thing is the antenna that either comes with the receiver or you connect to it. a cheap built in ferrite rod antenna will supply much less signal to the receiver than an external dipole or vertical. you can also get external preselectors and preamplifiers that can help your reception of weak signals.

1093. Snap-on choke hurts shielded loop

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-12 17:14:37 UTC
From: Loopfan <bgreer1@earthlink.net>
Message-ID: <1mXPa.43439$C83.3440878@newsread1.prod.itd.earthlink.net>
Source record: 112737

I performed an interesting shielded loop experiment today with a snap-on ferrite rfi-choke:

1) When the choke is placed anywhere on the coax feedline the choke has no affect whatsoever.

2) When the choke is snapped anywhere around the loop-element coax, it really attenuates the loop signal, and also detunes it. I had to readjust my tuner's capacitor quite a bit. It also seemed to flatten out the nice sharp Q. It did not affect the directivity however. Placement of the choke anywhere on the loop element seemed to produce the same amount of attenuation - from right over the gap to anywhere else on the loop.

Unless I misunderstand how ferrite-chokes work, this does seem to physically point out that the shield is the actual antenna. (This is what I've been told all along here.) Nobody in their right mind would place an RFI choke on their transmission line in an effort to reduce common-mode radiation if it also severely attenuated the wanted signal right?

Am I on the right track? The correct theory is nice to know, but it is also great to see it proven physically....

I use my communications receiver for that purpose. I listen to far away
talk radio shows and often switch from AM to SSB filtering to decrease
the interference problems. Switching between USB and LSB sometimes helps.

Cecil, W5DXP wrote:
"What caused the rearward traveling current to go to zero?"

The rearward-traveling current did not change phase on reflection from a load of too-few ohms. Only the volts reversed phase on reflection. The amps never changed nor do they need to change phase for re-reflection.

The re-reflected volts and the re-reflected amps need to be in the same phase as are the new volts and amps to merge seamlessly with the new energy in the return assault on the load.

The volts do need a phase reversal for reversal of wave travel when the current is not reversed.

You can find good deals ($1.00 to $20.00) on good used car radios at garage sales. People buy radios with CD players and dump the cassette or no cassette versions. Get one, perhaps like the one in your car which you know works and buy a 12 volt supply, speaker, and a long piece of wire for an antenna and your in good shape. I've done this several times and what I like is that I have pushbuttons for my favorite AM and FM stations. Great sound too if you get good speakers, you can find those at sales also.

True, there is a re-reflection event exactly as you describe. But the
reflection coefficient for that re-reflection event is not 1.0 so not
all of the reflected power gets re-reflected. What happens to the rest
of it? How do you explain the discrepancy between the physical reflection
coefficient less than 1.0 and the apparent 100% re-reflection of reflected
energy at a Z0-match point?

I'm not sure if that's meant to be humorous, or if you really did misinterpret what I meant. In case it's the latter, I'll amplify.

If a quarter wavelength shorted stub at frequency f1 has impedance R1, then a quarter wavelength shorted stub at frequency f2 will have an impedance of R1 * sqrt(f2 / f1), if it's made of the same type of transmission line, and the frequency is in the range where conductor loss dominates (below about 1 - 10 GHz for typical coax).

Whoops, I really did misinterpret what you meant. When you said, "All
else being equal," I inferred that you were including the physical
length of the stub. Changing the length of the stub didn't seem to
match the condition, "All else being equal,". Sorry.

1103. Re: Snap-on choke hurts shielded loop

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-12 21:12:33 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <vh0ue4ceabc831@corp.supernews.com>
Source record: 112747

Yes, you're on the right track.

The reason the ferrite choke on the antenna flattened out the nice Q is that the impedance of many ferrites is fairly resistive (lossy) at HF. This is fine, and even desirable, for making broadband transformers and baluns (unless high power is involved). So when you slip that ferrite core over the antenna, it's just like you've added a series or parallel RL circuit in series with the antenna at that point. If you're curious about how much R and X you're getting, you can easily measure it if you have an antenna analyzer. If you use a relatively high frequency ferrite like one of the Fair-Rite 60 series, it'll look more like a low loss inductor, so it would detune the antenna but not broaden it much.

There are three distinct currents flowing in and on a coax cable. Currents on the outside of the inner conductor and the inside of the shield are always equal and opposite, providing the shield is effective. (Typical coax shields begins failing at low -- audio-ish --, not high, frequencies.) A third current can flow on the outside of the shield. The ability to radiate or receive a signal depends on the vector sum of these currents. The vector sum of the two inner currents is always zero, making the vector sum of the three simply equal to the current on the outside. A coax cable with no current on the outside will neither radiate nor receive a signal (except, of course, from the relatively small leakage due to shield imperfections). A ferrite core on the outside of a coax transmission line presents an impedance to the current on the outside of the cable, thereby reducing it. The currents on the inside remain equal and opposite, and aren't affected by the core.

In the case of a shielded loop, the current on the outside of the antenna coax shield is necessarily and intentionally equal to the current on the inside of the shield -- if you forced the outside current to zero (by closing the gap, for example), the antenna wouldn't radiate or receive. Putting the ferrite core on the antenna coax reduces that current, hence reducing the antenna's ability to receive or radiate.

>insulation is OK for the choke balun?

Sure, it should be fine. As with any coax, you should check the power
rating (lest you arc the cable or overheat it in use, but you
shouldn't have this problem with RG8 at reasonable power levels).
And, for the lengths we're talking about here, and at HF frequencies,
I suspect that RG8 may be overkill - you could use RG8X "mini" coax
and the losses would be quite tolerable.

>Somewhere in the back of my mind I remember seeing something about the cons
>of foam insulated coax. Am I getting paranoid?

Well, I believe that foam-insulated coax may be a bit more prone to
wick up water if you don't seal the connectors properly and the rain
starts to fall ;-)

For indoor applications this shouldn't matter. Just buy a 10-15'
piece of RG8 with PL-259 connectors on it, use a barrel adapter to
connect this to your existing run of coax, roll up the choke balun,
and you should be fine.

Hi all

Was wondering if there is anyone out there who can help? I have just purchased a 7 element ATN 18-30-7 log periodic that covers 18-30Mhz. I believe there is another ATN aerial with the same boom length of 6 metres that covers 14-30Mhz. I was hoping someone with one of these beasts could advise the element lengths etc so i can convert mine to cover 20metres. I assume i will need to rearrange the elements, drill alternate mounting holes and change some element lengths and make some crossover straps for phasing harnesses but thats just a formality. My aerial comes with a diagram of the element lengths etc so was hoping someone could scan and send. I could start from scratch and try and design a unit but this would save me a heap of time. It appears that ATN is long gone. Any help would be greatly appreciated. I have quite a collection of amateur radio related service manuals in pdf and or jpg format so maybe i can return the favour.

email for reference is tstone12002@yahoo.com.au

Thanks in advance.
Cheers
Tony

Hello all,

I have a 6m transverter on the way this week to use just in time for the CQWW contest this weekend... one problem NO ANTENNA!!

So I picked up a very old Yagi, built in 1969, but still in great condition. Its currently cut for the 40 MHz band, so I should be able to trim the elements down and change the spacing for a 3-element 6m antenna, right?

At any rate, the information I have been able to find so far (from various Yagi calculators found online such as that found at http://www.csgnetwork.com/antennae3ycalc.html) give the following figures:

Calculated Driven Side Element Length 4'6 19/32"
Calculated Total Driven Length 9'1 6/32"
Calculated Reflector Length 9'7 5/8"
Calculated Element Spacing 3'7 7/32"
Calculated Director Length 8'6 23/32"

Here are my questions:
1. Can I do this? Cut the elements, change the spacing.
2. What does "driven side element" length refer to? Is this the "matching dipole" (gamma match) part of the driven element?

Are there any unexpected snags/pitfalls I should look out for?

Thanks,

Jason

Well I use a Tennadyne T8 for 13.5 to 30 MHz. It is a 6 meter [18 feet] boom. I am not familiar with the ATN 18-30-7 LP.

But, LP design is based upon a specific ratio for adjacent lengths and element spacing. So, just 'fiddling' with adding elements and adjusting spacing gets to be serious business. You will have to re-space ALL elements on the boom, and increase the length of ALL the elements to achieve the desired ratios.

The ARRL Antenna Handbook has an excellent section on LPs. Buy or borrow a copy and read up on LPs. It's quite a project!

How can the shield be the antenna when it's connected to RF ground?

Jason -

Do you know who made the original Yagi? Is it aluminum tuning or solid rod?

The fastest method is to shorten the reflector, director and driven
elements, BUT
maintain the element spacing. Later - you can look at changing the element
spacing - if desired.

Dear Tony (VK2TS):
Nice to see a real antenna question from an actual radio amateur...
It seems to me that two of your choices are:
1. Distributing seven elements on the same boom using the same attachment points. All except the front (smallest) element could be lengthened by a constant ratio so that the rear (longest) element is self resonant at about 12 MHz. An estimate for the ratio by which elements are lengthened may be found by dividing 18 by 14.
Seven elements to cover the octave you are interested in on a six meter boom is OK, but a longer boom and a few more elements can provide less variation in VSWR with frequency and more gain.
2. It sounds as if the boom you have is of one piece. [One alternate scheme for the boom of a LPDA is to construct the boom in two pieces so that the boom is also the transposing transmission line.] I say this because you mention "crossover straps for phasing."
Thus an alternative is to leave what you have alone and extend the boom. Place additional elements along the extension spaced with the same ratio presently used and having lengths that progress with the same ratio presently used. This might involve the least amount of work and certainly would produce a better antenna. The extension of the boom might be a size larger than the present boom so as better to support the longer elements and so as to facilitate "splicing" to the present boom.

Extending is what I would do.

Seem like a waste of a good Cushcraft 13B2 (13 element yagi) 2 meter antenna
($ 150 MSRP)
for 440 MHz antenna. http://www.chq-inc.com/cush/13B2.html

What are you trying do on 70 cm ? (440MHz) SSB/CW DX, FM repeaters, ATV,
satellite work

1. When you move from 2 meters to 70 cm -- the coax you use from you
operating position to the antenna
becomes much more important than at HF or low VHF frequencies.

For example, for 100 feet of coax the attenuation in dB [from Cable X-perts
charts]
http://www.cablexperts.com/cfdocs/cat.cfm?ItemGroup=3&itmsub=0&bskt=0&USA_ship=1&c=0

RG-213/U at 150 MHz - 2.8 dB; at 450 MHz - 5.2 dB
LMR-400 at 150 MHz - 1.5 dB; at 450 MHz - 2.7 dB

2. Some designs to consider !

K5OE 70 cm yagi designs (in this case for AO-40)
http://members.aol.com/k5oe/P3D_ant/P3D_yagi.htm

VK3KHB 8 element design for ATV usage
[Uses 1/8" (~3 - 5 mm) solid rod for elements and round or square aluminum
tube (~ 10 mm)
http://www.gak.net.au/vk3khb/atv/antdesign.htm

WiMo products [Germany] - great for ideas
http://www.wimo.com/verteiler-e.htm?s1_e.htm

KK5UFO designs
http://www.homestead.com/kk5ufo/VHFbluprint.html

XE1MEX design (for 2m and 70cm)
http://xe1mex.gq.nu/antenas/yagi.html

Martin DK7ZB very nice designs
http://www.qsl.net/dk7zb/start1.htm

Derek, G4CQM
http://www.g4cqm.btinternet.co.uk/antennadesigner/yagis.htm

That's a start !!

If you do this. Don't assume the main lobe will be straight ahead. I have used a 7 el Cushcraft on 432, and found its best direction was about 30 degrees to one side. It had a gamma match.

Cecil, W5DXP wrote:
"But the reflection coefficient for that re-reflection event is not 1.0 so not all of the reflected power gets re-reflected."

100% re-reflection was a given. It is my assumption and I`m sticking with it..

Cecil introduced the idea of total re-reflection when he posed a problem of 1/2-wave of high impedance line imbeded in a 50-ohm system. The idea was that no reflection was presented to the transmitter by the 1/2-wave because it presents 50 ohms to the transmitter.

Where the transmitter meets the 1/2-wave, re-reflection within the 1/2-wave is complete. That`s possible regardless of the impedance the transmitter presents as a practical matter because the transmitter makes the reflection happen. I`m tired of explaining something cecil refuses to accept.

Best regards, Richard Harrison, KB5WZI

>
>Regards, Ad

When aligning the antennas you must swing each all the way left and
all the way right to where you are well past the beam width and any
lobes. Of course you note the signal strength as you do this. That is
the only way to be sure that you are not on a side lobe. Just moving
it a little each side of a peak or even moving it until you loose the
signal is not sufficient. You could hit a null between the main and a
side lobe and think that you have gone far enough but you still could

peak on a side lobe.
By swinging way past the lobes, each way, and noting the signal
strength as you go will assure that you find the main lobe.
Do the same in the vertical plane also.

I apologize for the lower-case "C" used to initiate the last "Cecil" in my most recent posting. My finger must have been tired and weak when I hit the shift-key. No offense was intended.

It`s fixed phase and high transmitter volts which thwart energy return to the transmitter according to my profs over 50 years ago in circumstances posed in the problem I was considering. It seems reasonable when the stand-off happens at an impedance discontinuity.

Best regards, Richard Harrison, KB5WZI

The elements are "solid rod" I believe. What are the consequences of not changing the spacing, while cutting the elements to the right lengths? Loss of directivity would be my guess, but I'd still have a good radiator with relatively low SWR?

Thanks,

Jason

Jason -

With solid rod elements - you are in a "measure at LEAST twice and cut once"
situation.

Most likely the directive lobe would not be optimized.
You can use antenna modeling software to see the specific results, BUT this
gets you on the air quickly.

Ad wrote:
"Anybody can explain where I go wrong?"

Too much worry, too little preparation.

You survey the path, ensuring freedom from obstruction and adequate clearance for Fresnel zone and anomalous propagation based on reliability demanded. Figure the azimuths for the dishes, lay them out with an instrument and put a stake in the ground on the path where it is visible from the antenna mount.

If the path isn`t trivially short, set the dish feed elevations with a bubble level to the horizontal.

Set the dish azimuth toward the stake driven in the path direction.

Turn the radios on. Apply an audio tone directly on the transmit baseband at both ends. Set the tone level almost to the maximum composite signal baseband lervel. Listen for the received tone in the order-wire speaker at each end. It should already be there. Now it iis just a matter of refining the antenna adjustments at both ends. On FM radios, limiter current is the usual indicator of signal strength. On other radios use whatever signal strength indicator there is. My practice has been to give the tower guy a repeater meter so he can optimize from his own observations while the ground operator advises.

One path end is adjusted at a time so it`s known who is making the path changes.

Sometimes it`s necessary to hunt for a tone by slowly sweeping the azimuth, but it`s rare.

You can believe it or not, but I`ve done path alignments countless times and the method described has always worked for me. It makes no difference which end is aligned first if you detect a signal to start with.because antennas and path propagation are completely reciprocal in all but the rarest cases.

Best regards, Richard Harrison, KB5WZI

"Do the same in the vertical plane also."

Never had a minor lobe identification problem.

Never improved over the bubble-level set of vertical elevation angle on long paths either, but I always tried.

I had always calculated my path gains and losses, and my best received carrier power was very nearly always within a db of my calculations. If not, I had a problem. Fortunately, that was very rare.

Best regards, Richard Harrison, KB5WZI

Did you actually do very many?

The reason I ask is that there are other factors, and you
can't calculate them, and in some cases you can't even
adjust for them.

The best example that I know of was a TV microwave repeater that
was put in north of Tucson for a link between Tucson and Phoenix
back in the 1960's. This thing was located 50 miles from town,
at 8500 foot on a mountain top. They had a 50 foot tower
installed on a concrete base that cost $50,000 (think about that
in today's money!). And when all was said and done, they turned
it on, and it worked great!

But somebody had the smart idea to see what happens if they
slide the dish down the tower to see if the signal would
improve. It did!

So they positioned it vertically on the tower for best signal
strength. About 7 feet off the ground... :-)

(And darned if a few years later a build up of rhime ice on the
43 feet of tower above the dish didn't fall down and bend that
dish into a pile of ruble too.)

> Calculated Element Spacing 3'7 7/32"
> Calculated Director Length 8'6 23/32"
>
> Here are my questions:
> 1. Can I do this? Cut the elements, change the spacing.

Are you sure that it is cut for 40 MHz, and not 40 meters? What service
uses 40 MHz anyway?

If the yagi is really for 40 MHz, then I would just cut the elements to
length and not worry about the spacing, as there is a fairly wide range of
working spacing values. The only thing that would be changed is your
radiation pattern. If the yagi was originally for 40m, you will need to do
a lot of trimming, and will need to adjust the spacing.

> 2. What does "driven side element" length refer to? Is this the "matching
> dipole" (gamma match) part of the driven element?

No, it refers to the length of each leg of the driven element (which is a
dipole)

Floyd Davidson wrote:
"Did you actually do very many?"

I`ve done single-hops, several-hop systems, and transcontinental systems. I`ve done them on-shore, off-shore, and in a multi-hop loop system on-shore and off-shore. I`ve done several systems with paths sandwiched between tall buildings. I`ve done 960 radio, 2-GHz, and 6-GHz systems. I`ve done space-diversity systems, hot-standby, and unprotected systems. I`ve done solid-state systems, vacuum-tube systems, etc., etc.

I have no reason to say anything which is untrue. Floyd knows of an anomalous hop in the desert. The path suffers reflections, else it would not have great variation of signal with height. I know of many anomalous systems, but I never built one. All of mine worked as designed.

Best regards, Richard Harrison, KB5WZI

==========

What would you like calculate ?

What is your definition of 'bandwidth' ?

Are you concerned only with what the SWR meter is supposed to be measuring ?

Bandwidth depends as much on transmission line and matching arrangements, if there are any, as on the V itself. Changing the apex angle is just as likely to increase as to decrease bandwidth, depending on what it is before any changes are made.

Download from following website in a few seconds program INV_VEE and run immediately. It will estimate most characteristics of a 1/2-wave resonant inverted-V, including input impedance of the dipole and of the input impedance, R+jX, of the transmission line at the transmitter end.

BTW, although it may be possible to minimise SWR on the feedline by varying apex angle, overall result may be a loss in efficiency. Relative to a horizontal dipole the V has a lower radiation resistance and a higher ground loss resistance. The effects interact with each other. The program demonstrates. All dimensions and angle can be varied "What-if ? "

Alex -

40 MHz is within the "Land Mobile" allocation (low band VHF - within 30 to
50 MHz),
which has existed at least since the 1940s (post World War 2).

Here is the NTIA - U.S. Frequency Allocation Chart
http://www.ntia.doc.gov/osmhome/allochrt.html

My father had a commercial radio system at 46 MHz from 1957 to 1990.
The Illinois State Police used 42.xx MHz for their District office stations
for over 50 years
and many of their mobiles (long whip antennas) well into the 1980s and 1990s

As I pointed out, that was the most _interesting_ example that I
know of.

However, you've just stated something that I can't quite get my
arms around. "All of mine worked as designed." is stated as if
the "anomalous systems" that have a path which "suffers
reflections" are somehow not common, or not well designed, or
not normal.

Yet you mentioned "on shore" and "off shore" each twice above,
and I'm having a real difficult time thinking you've ever
designed a microwave shot across tidal waters without having
"reflections" which could not specifically be calculated. And
there is simply no way that it "worked as designed" unless you
mean you just allowed for a large enough fudge factor to account
for signal swings from day to day. The original claim that they
all came in within 1 dB is just hilarious.

My bet is that you have hung around and do know how these paths
function over time, and I'll bet you just exaggerated a little,
that's all.

Dear Tony: You are welcome.
What might, or might not as I have only minimal information, prove to be the easy way to scale the new elements is to realize that the tips of the new elements will be close to being in line with the tips of the "old" elements. This is close enough particularly if, to maintain the principle of each element being designed to fail with the same amount of wind/ice pressure, the majority of the ends of the new elements are of the same diameter as those of the "old" elements. In other words, if the original antenna was designed to the above principle, the new elements will look like the longest "old" element with added buts that are larger. Having the additional boom be the next size larger than the old boom facilitates this and the splicing of the booms. Consider a "plastic" rope strut to stiffen the boom.
Ice may well not be a major consideration for you as it is here. However, a few years of wind induced vibration has a tendency to damage the places where the longer elements are attached to the boom. Internal and/or external boom/element sleeves in those areas can extend the lifetime significantly.
Keep us all posted on your progress. Several of us will be interested in the specifics of the original antenna.

<< What are the groups thoughts on an off center feed antenna being 41 feet long on one side and 96 feet long on the other side. The feed point is a 4:1 balun and then any length of coax to the tuner. How is it for a comprimise antenna for all the bands 80 meters to 10 meters ? >>

Ralph-

When I started in the mid-50s, a popular antenna was the "Full Windom". It was an off-center fed dipole, fed with 300 Ohm twin lead, and was as popular then as the G5RV is today. Its length was 135 feet, but I do not recall the offset. I think yours is close enough to call it the same antenna! (Note: The original Windom was NOT a dipole, but a wire fed off-center with a single wire. Ground was the other antenna terminal!)

In my case, I fed the 300 Ohm twin lead all the way to the shack. My earliest rigs were link-coupled, so the link was balanced as long as one side wasn't grounded. Later, I advanced to a tuner with a coil that had balanced taps for connection to the antenna. Others used BalUn coils and co-ax, which I couldn't afford at the time.

The wisdom of the day, was that the Windom was all-band but wouldn't work on Twenty Meters. I used mine mainly on Seventyfive and Forty Meters. It may have worked on Twenty, but I don't recall trying it. I believe it also worked on Fifteen Meters, but I didn't have a receiver that worked well there.

Hello...

I am looking to install either a dipole, or just a long wire, and need suffestions on a tuner. I am running an amp, 700-800 watts out max. The SGC 235 has a max input of 500 watts (no, I am not lowering the power, sorry). So, Who makes an automatic tuner that handles 1000 watts, and can be mounted outdoors, at the antenna feed-point?

Sunair came to mind, any info on these, where to obtain, how to control it, etc? Any others? Harris?

Thanks

Bob-

Where does the Co-Ax connect?

Based on other Two Meter J-Pole designs, I would guess that the Co-Ax connects about two or three inches from the bottom of the "J" matching section, with shield connected to the main element and center conductor connected to the matching arm. For Six Meters, perhaps the connection would be about six inches above the bottom. If you used stainless steel hose clamps to attach the cable, adjustment would be easy.

Interesting. Just the other day, we were told that 10 dB wasn't enough signal strength difference to worry about, and even ol' "Kurt Sturba" has said that a mere 18 dB isn't that big a deal. Now here we have someone who feels that an extra 1.5 to 2 dB is worth considerable trouble and expense. Just goes to show ya.

Floyd Davidson wrote:
"---I`ll bet you just exagerated a little, that`s all."

Too many hours of daylight on Floyd are taking their toll.

Everything you work with is known. precisely, including path attenuation under normal propagation conditions. Normally, you don`t have a path grazing at a highly reflective point. Your path survey discloses path detractions and you adjust for the possibility of distructive interference. You may opt for a high / low antenna placement for the path ends, diversity, more clearance, shorter paths, and brute-force fade margins. The high / low option lets you move the reflection point and the reflection. Long microwave systems must have huge fade margins anyway due to noise buildup from individual path contributions. A receiver not too much below the overload signal point is a very quiet receiver and contributes almost no noise to a system.

When the path design is right, the as-built numbers are almost exactly as calculated, whether you believe it or not.

Best regards, Richard Harrison, KB5WZI

And my question is, in the absence of a physical reflection coefficient magnitude of 1.0, what causes 100% re-reflection?

> I`m tired of explaining something cecil refuses to accept.

I accept everything you have explained, Richard, but you have not answered my question. What causes 100% re-reflection? Please be specific. A voltage to current ratio is a result and not the cause of anything.

Here's a question for you, Jim. How much power is transferred from the
mismatched load rearward by Pref2?

source---50 ohm feedline---+---150 ohm feedline---load
Pfwd1=200W --> Pfwd2=133.33W -->
<-- Pref1=100W <-- Pref2=33.33W

If, as you have asserted, Pref2 can transfer zero watts when it measures
33.33W, can it also transfer 100W when it measures 33.33W?

Lets see, now you are saying that you go out and *measure* the
path, rather than calculate it.

And of course you measure it, *every* *single* *time*, on a day
when you *know* whether it is giving you the best path, the
worst path, or some specific point in between.

Richard you can cut the bullshit out. I've been measuring
microwave paths for 40 years. You don't calculate them to
within 1 dB. You might find out what that is after measuring it
on a regular basis for a year. (I've done *continous* path
measurements of several paths for over a year, and on two for
10 years.)

Cecil, W5DXP wroyte:
"Why doesn`t the same thing happen 1/2WL back up the line where the impedance is exactly the same?"

Uniform distribution of inductance and capacitance 1/2WL back up the line.

John E. Cunningham in "The Complete Broadcast Antenna Handbook" wrote as I recall, an attempt to explain the reflection operation on a transmission line as caused by impedance discontinuities.

If I recall, he said a short on a line vitiates capacitance at that point. It shorts it out. Increased current in the final segment of the line inductance sets off the reflection. The extraordinary volts generated, reverse the wave direction and reverse the phase of the volts. What happens to the current is a turnaround sooner than later, but it still comes and goes in the same phase.

The discontinuity is essential to the turnaround. Lacking a reduction point or growth point in inductance to capacitance ratio, you lack an essential to generate the reversed signal. That`s why the virtual short does not turn the signal around. It has no discontinuity.

Best regards, Richard Harrison, KB5WZI

> Which item to input if antenna is on
> a roof?
-----------------------------------------------

If it's corrugated iron then enter 0, Sea water or Very good.
If it's timber then enter 500 or Very Poor.

-----------------------------------------------

> H: Height of ends, metres ......
> Is it the height from feedpoint
> and the roof or from feedpoint
> and ground?

----------------------------------------

Nothing to do with feedpoint.

The 'ends of the wire' are the ends of the wire.

Height of the ends above ground level is the height of the ends above the
roof - which so far as the antenna is concerned IS the ground.

Raise the height of the ends by 1 metre and the whole triangular shape,
including the apex, increases in height by 1 metre. That way you have
nothing to worry about. The length of the dipole and the apex angle remain
unchanged.

To vary the apex angle, vary the straight-line distance between the dipole
ends and the dipole length will remain unchanged.

Input variables can be swept by up/down keyboard keys between their extreme
values. All can be done in a second or two.

Set the apex angle to 180 degrees and you have the performance of an
ordinary 1/2-wave resonant dipole with its feedline, either coax, ladderline
or open wire.

Hi Doug

ie like half a rhombic?

I remember the ARRL antenna book has a graph of wire wavelength vs gain/lobe performance. Cant imagine it being to much more difficult than that.

Possibly a websearch on rhombics? Might cover the development/theory.

http://www.mindspring.com/~cummings7/rhombic.html has a link at the end to a Windoze pgm that calculates best wire angles... I didnt try it...

Cheers Bob VK2YQA

Floyd Davidson wrote:
"Richard you can cut the bullshit out."

Floyd claims to have measured microwave paths for 40 years. I`ve been doing it since 1960, so that`s about as long.

I`ve made repeated measurements over a number of years on the same repeaters. During normal propagation, which is by far most of the time, path loss like other system losses is very constant.

Of course there are periods of anomalous propagation. It depends on location, season, and time of day. It`s worse when the atmosphere is stagnant.

I`m sure that marginal paths with insufficient clearance and other problems may have propagation which comes and goes. I`ve seen some, but I haven`t built any like that.

Best regards, Richard Harrison, KB5WZI

Depends on the length of the wires. Usually ranges from about 70-75
degrees for a V beam 2 waves long, down to about 28 degrees or so for
a 12 wave long V beam.
A V beam 8 waves long would be best around 30-35 degrees or so. There
is info on V beams both in the ARRL ant handbooks, and also the Bill
Orr radio handbook has a section. Dunno about the web...MK

If you have room, you could slap 40 legs onto the same coax in
parallel. 20m also if you wanted. The good part about doing that is
you get normal dipole performance and pattern on both the bands if at
right angles. No compromising on efficiency.
Even if not at exact right angles, it would work fine. Many of mine
are like stretched "X's", or butterfly wings. MK

If it were for 40 mhz, the spacing at 50 mhz should be usable as is I
bet. What I'd do is model the antenna with the current spacing, but
with the new element lengths and see what the pattern looks like.
Being the boom is longer on a 40 mhz beam than the 50 mhz, you have
the potential to have a long boom antenna. If the 40 mhz beam was a
"short" maximum f/b ratio antenna, it might be about right on 6m as a
max gain antenna. My 6m beam is 3 elements and copied after the NBS
yagi. The boom is 8 ft long. It's set up for maximum gain and mediocre
f/b ratio. But many people use a 6 ft boom on a 3 el 6m yagi to have
a better f/b ratio with slightly less gain. The spacing is not overly
critical just to operate with decent gain. But you could respace if
you decide to optimise the antenna for your exact wants. My beam is
exactly copied from the one in the elnec or eznec demo. "NBS yagi"
It's 1/2 copper tubing same as the model. The real world results
closely matched what it modeled. MK

Thanks for all the responses and suggestions on this one. After fiddling around over the weekend, I still don't have a definite answer, but thought I'd let you all know the status.

I tried various lengths of coax in the line to see if that might have had something to do with it, but with no difference to the SWR minimum frequency (note, I don't say "resonance" anymore :-). I used lengths ranging from about a foot and a half, to eight feet, to a twenty foot section. I also stuck a couple of different SWR meters in the line, and at various places along the lengths of coax. Still no changes from the normal reading. It's only when I put the MFJ tuner in the line that things go wacky.

Anyway, the bottom line is that the tuner will be useful for feeding balanced line or single-wire antennas. But I won't be using on any coax-fed antennas that are already somewhat well-behaved. My best guess at this point is what David Robbins suggested, i.e., the tuner's throwing some wierd impedance bump into the line which results in this peculiar effect.

Too late for it now I guess. If you know the frequency of the antenna then
you can devide it by the frequency you want to operate on and change the
lengths and spacings by the same fraction. Then if gamma matched adjust the
gamma for a low swr.

But there is NO actual short. The ratio of voltage to current is not
even zero. The ratio of voltage to current at a Z0-match point is Z0.

> The discontinuity is essential to the turnaround.

Exactly! That's how b1 = s11*a1 + s12*a2 gets to equal zero. s11*a1 and s12*a2
are both reflections from the physical impedance discontinuity. No "virtual
short" required. s11*a1 and s12*a2 are reflections that are equal in magnitude
and opposite in phase.

Ralph,
You bring up a very valid point-- SCALING! This is an old trick I forgot
about, but I'm certainly glad you mentioned it.

One question-- this antenna has a gamma match-- how does the gamma match
change with respect to all of the other new dimensions?

Not to sound too smart about it, but it beats me. I have only messed with one gamma match and it was on a 6 meter factory beam. I would guess that a good starting point would be to scale the shorting point and then adjust the capacitance for the lowest SWR and move the short again if necessary. The spacing of the gamma rod to the driven element will make a small differance also.

So now you say it's constant except for when it's not! Your designs
are within 1 dB except when they aren't.

I *am* impressed.

>I`m sure that marginal paths with insufficient clearance and other
>problems may have propagation which comes and goes. I`ve seen some, but
>I haven`t built any like that.

That's why I asked if you'd built many.

In fact it is quit common, and most paths have anomalies. Most of
course aren't very interesting. But others are. Suggesting your
designs have never collided with such an anomaly just means you
either didn't really do many or you're failing to recall them.

Floyd Davidson wrote:
"Suggesting your designs have never collided with such an anomaly just means you didn`t do many or you`re failing to recall them."

It means care was taken in path planning. Microwave propagation is very predictable. The only variable is the atmosphere and long statistical records are available which allow a design for a percent reliability, 99.99 out to the limit of your budget.

Of course, on any particular path, there will be fades on some foggy morning, but that doesn`t guarantee failure if you`ve planned for it. The phone company uses alternate routing. I`ve designed similar systems.

What I said was, the as-built hops performed as designed during normal propagation. That`s nearly all of the time. The received carrier power measures remarkably close to the predicted value nearly every time and if it doesn`t when the the alignment is complete, in my experience, it has been always due to a defect in the system, not in its design..

I have never had to go back and "beef up" a hop to obtain reliability, and I`ve put some hops in tough territory. The arithmetic is simple and so are the criteria.

Best regards, Richard Harrison, KB5WZI

Cecil, W5DXP wrote:
"The ratio of voltage to current at a Zo-match point is Zo."

There is one voltage at a match point produced by the waves arriving from opposite directions.

There is one power, the power delivered by the transmitter, feeding the match point. The same power total flows from the match point to the load. It`s the forward power minus the reflected power.

Though there is but one voltage at the match point, it is clear that the currents in lines connected at the match are not equal because the Zo`s of the connected lines are not equal.

We need the reflected power to reconcile our mismatch. The mismatch is a catalyst that makes a reflection happen.

Say Zo is 150 ohms. 100 watts into Zo is 123.5 volts. 10 watts facing the 100 watts presents 38.7 volts. Power direction is determined by the 123.5 volt source, not by the 38.7 volt reflection, at the match point.

Best regards, Richard Harrison, KB5WZI

Floyd also wrote:
"But somebody had the smart idea to see what happens if they slide the dish down the tower to see if the signal would improve. It did!."

I wasn`t there, so I can only speculate, but I might have not been surprised by those results.

On a 50-mile path with plenty of mid-path clearance, propagation is similar to communications with a satellite. One difference at the Arizona latitude is the vertical angle the dish path makes with the Earth. The low angle the dish on the terrestrial path makes with the Earth, makes it vulnerable to reflections from the Earth. The higher the dish is placed, the more vulnerable it becomes. That`s a reason to go high / low on a reflective path, and not high/high. (Low/low won`t make the trip on most long paths due to Earth curvature).

There's a world of difference between a resonant antenna and a resonant antenna system!!

BTW, is a Log Periodic Antenna, example Tennadyne T8, resonant across the frequency range of 13.5 MHz to 30 MHz?? No tuning required on any frequency between 13.5 and 30 MHz, and VSWR <1.7:1 across the range!

Reg, G4FGQ wrote:
"All antenna "systems" are resonant because they present a resistive load to the transmitter. QED."

Reg is right but there are of course exceptions.

"Standing wave antennas", those like dipoles which have refllections at their ends, are tuned to rid them of reactance which would oppose incoming antenna current.

If the antenna is operated off-resonance, it still works but with less vigor due to diminished current opposed by inherent reactance.

There is a class of "traveling wave antennas" which are terminated, not in an open or a short, but terminated in their Zo`s to eliminate reflection from their terminations. This avoids radiation which would be caused by the reflected energy and change the radiation pattern produced by the forward energy. It also eliminates a change in the antenna drivepoint impedance caused by arrival of reflected energy back at the drivepoint. This reduces drivepoint impedance change as the frequency is changed.. This can make an antenna more acceptable to a radio over a wider frequency range, but it is likely to make the antenna less efficient.

Very broadband antenna systems, such as log-periodics, are still resonant.
They are a collection of different-frequency resonant elements.

Another way of looking at it, a collection is broadband because as a whole
it has a very low resonant Q.

Resonant circuits have an effective Q or a collection of Q values even when
the impedance-frequency response is flat-topped. (As inside a double-tuned
455 KHz IF transformer can.)

At sufficiently high and sufficiently low frequencies the reactive component
of the input impedance always predominates.

The definition of resonance as being adjusted to present a resistive load to
the transmitter should not infringed.

Of course, it is quite possible to operate a transmitter with a non-resonant
load, ie., the load impedance having a reactive component in addition to the
essential resistive load. But if only for economic reasons this condition is
nearly always avoided.

Reg.

A time-varying (RF) magnetic field generates an EMF in any loop
surrounding it.

(Faraday's Law of Magnetic Induction: there is an EMF proprotional to
the rate of change of the magnetic field enclosed by any closed line.
Ohm's law: the voltage drop in a resistance is proprotional to the
resistance and to the current. Kirchoff's Voltage Law: the sum of
voltage drops around a closed loop is equal to the sum of EMFs in the
same loop. Edwards' Law Quotation Law: Anyone quoting laws is not to
be taken too seriously. Or something like that. So by making the
loop a conductor with a gap, the EMF given by Faraday's law is
delivered almost completely to the gap. Doesn't matter if the loop
conductor is grounded at some point or not. Note also that in the
presence of a time-varying magnetic field, the voltage you measure
between two points depends on the path you take.)

Cheers,
Tom

Essentially all you are saying is that net energy flows from the source
to the load. I agree but it has nothing to do with "facing off". Coherent
voltage waves flowing in opposite directions are unaffected by each other.
Coherent voltage waves flowing in the same direction merge into one wave.
The events that happens at an impedance discontinuity are reflections which
causes coherent waves to flow in the same direction and therefore merge. It
is explained in my part 1 article on my web page.

Actually, when the transmitter circuitry folds back, it means that the
antenna system is not resonant. When I change bands with my screwdriver
and start tuning, my antenna system is certainly not resonant.

This is true only if no effort has been made to match the antenna to the transmitter. If it's matched, it will have the same current and "vigor" as a resonant antenna. Assuming negligible loss, if 100 watts is applied to resonant and non-resonant antennas by any means, 100 watts will be radiated from each.

Just parallel them. The 440 should have a high impedance on 220 and the
200 should have a high impedance on 440. The frequencies that you have
to worry about are the 3x frequencies, i.e. 148 x 3 = 444.

First I have to know where it is being transferred. I don't see two ends of a path. Is there a load resistor hiding in a circulator somewhere? Is the 33.33 watts extra power that I could drive another antenna with, but is otherwise going unused?

Or is it instead, simply a field that is excited by the boundary conditions at the load that is being measured.

> source---50 ohm feedline---+---150 ohm feedline---load
> Pfwd1=200W --> Pfwd2=133.33W -->

The meter measures voltage, assumes a transfer of energy, and displays power based on that assumption.

Roy, W7EL wrote:
"This is true only if no effort has been made to match the antenna to the transmitter."

It is true with every transmitter which occupies more than zero bandwidth. Reactance is zero at one point in the frequency spectrum. Off-resonance, an antenna system accepts less current than it does exactly on resonance. But, the difference is usually less than 1 db.

I wrote that if the antenna is operated off-resonance (excited by a frequency other than its resonant frequency) it works but with less vigor etc.

If the antenna`s power factor has been externally corrected for some frequency other than its natural resonant frequency, then it is resonanat at a new frequency. Its vigor will not be subdued by inherent reactance at the new resonant frequency.

When I said an antenna operated off-resonance works with less vigor, I tried for a statement true with a solid rod without connections and in free-space, a receiving antenna, and a transmitting antenna, all operated at a frequency other than their resonant frequencies. All are transmitting antennas because they all radiate when excited, no matter how the excitation is delivered.

I think I succeeded in saying it correctly but failed in saying it well if it was misunderstood.

the 'proper' way to do this is with duplexers. these are basically bandpass filters that only pass the frequency you want from each antenna onto the single coax and prevent interaction between the two antennas.

the cheap way is to just connect the two of them with a T connector and hope for the best...

the experimenters way is to cut the coax between the two antennas and the T connector to minimize interaction. for this i would start with 1/4 wave at 440mhz feeding the 220 antenna, and 1/4 wave at 220mhz feeding the 440 antenna.... listen to a source on 440 with just that antenna and connect the 220 antenna and see if the signal drops, if it does add another 1/4 wave at 440mhz to the 220 antenna feed and try again, if that doesn't fix it try removing 1/8 wave... then hook the 220 antenna to the receiver and listen to a signal on it, connect the 440 antenna and see if the signal drops too much, if it does add 1/4 wave on 220mhz to it's feed line and try again... etc, etc, etc... if you have access to a network analyzer you can save lots of time. make it fancier by adding stubs and you end up building a duplexer in coax.

How about a "Gotham" vertical. This was about 20 ft. of vertical radiator, mounted on an insulator (often, the pipe was just placed on top of a coke bottle). A coil connected from the bottom of the radiator to ground (either a simple ground rod, or better with several radials). A tap was used to bring the coil/radiator to resonance. Another tap was used near the ground end of the coil to find about 50 ohms of match for the coax.

The last version of this antenna that I used was constructed from a flagpole bought at Sears.

A 50 foot tower on top of an 8400' mountain. What are you
talking about high/low etc etc. I wasn't there when the
decision was made to put it on a 50 foot tower, and neither you
nor I have any idea why that was done. Perhaps the topo maps
were wrong, and some obstacle they assumed was there didn't
actually exist. Perhaps the engineer made a mistake. I don't
know and you don't know. But, you don't suppose the engineer
knew exactly what he was doing, eh???

A 40 foot change in elevation suggests there simply were no
obstacles, so one has to wonder what the 50 foot tower was
supposed to accomplish... other than allow a range of adjustment
to find the best point for signal strength. Because this was
not a 50 mile shot, it was much closer to 100 miles and no doubt
they were very interested in optimizing the signal strength.
With no obstacles, not even earth bulge, calculating reflections
isn't so easy... unless you move the antenna vertically to find
the right position.

But, it doesn't emulate "a satellite" shot even in the slightest.
Or, not for real satellite shots at least.

E.g., the look angle for a geosynchronous satellite here is only
10-12 degrees or less depending on where the satellite is. I
don't agree at all that a 50 mile microwave path with no
obstacles is approaching similarity to a satellite shot! Some
satellite links have *less* clearance.

Of course, your exposure to satellites might not be that great.

==========

Wrong ! The antenna 'System' IS resonant, by definition, if it has a purely resistive input impedance. If that interfering nuisance of your fold-back circuit springs into action then it means the pure input resistance is something other than 50 ohms. But it is still resonant.

Actually, in YOUR case, the antenna is NEVER resonant. You make sure the antenna is NOT resonant by making the whole system resonant by varying the length of your transmission line.

Reg,

Reg, the chances of a foldback being caused by a resistive antenna is
about 1 in 360. Actually less than that because the transmitter will
not fold back between 25 ohms and 100 ohms.

Yes, and what we are discussing is exactly how an impedance bump
shakes things up.

Hi Reg,
That foldback circuit is an interfering nuisance agreed, but it comes in handy at times. My homebrew mobile antenna is difficult to keep tuned, much less in one piece doing 100 km/hr down the US Interstate system. My HF transceiver folds back if things are not right with the antenna system. The fold back circuits tell me I need to do something with the mobile antenna, before I smoke the final semiconductors in my rig. It doesn't tell me what I need to do, I use other stuff for that. I used a couple of your programs in the design of this beast, Thanks!

I'm used combiners with TV antennas in a stacked array. Two antennas
(on TV) is far better than one. Now if there was a 3 db loss in a
combiner, I would gain nothing as stacking gives about 3 db gain (on a
good day, down hill, and with a tail wind)

>> you had two antennas, each pointed in a different

It can be a bit of a problem if your antennas are below the top of the
tower, but I used an arm with the rotor mounted out from the side of
the tower by about three feet and get 240 degrees of rotation. It
just so happens all available TV stations are within that 240 degree
arc.

Floyd Davidson wrote:
"But, it doesn`t emulate "a satellite" shot in the slightest."

A satellite is a microwave repeater in the sky which is usually not susceptible to earth reflections.

Terrestrial microwave paths are often designed to minimize earth reflection.

Reason is, on a long path, the lengths of the direct ray and the Earth reflected ray are almost the same. Reflection reverses the phase of the reflected ray so that the reflected ray detracts from the direct ray when they combine at the receiver. They arrive out-of-phase, at least at some antenna altitudes.

The phase of the signal undergoes 180-degrees of phase change as we examine the signal either forward or backwards from the plane of the signal. That is to say, the phase of the signal is a function of distance along the path. When a second signal source is created by Earth reflection on the path, the combination of the direct and reflected rays produces strata of stronger and weaker signal intensities as altitude changes. No reflected signal, no significant variation of signal with altitude, given sufficient path clearance. This is a worthwhile design goal.

No matter which end of the TV relay path was varied to produce a significant signal strength change, the attenuation at the higher elevation was probably caused by an Earth reflection. Another reflecting surface near the microwave path could have been the reflector. I`ve seen that in the city canyons I`ve had to squeeze signals through. But on most paths, the Earth is the most likely reflector.

Best regards, Richard Harrison, KB5WZI

The 33.33W is associated with the s-parameter term, a2. So it splits
into s12*a2 and s22*a2. s12*a2 becomes associated with b1 and s22*a2
becomes associated with b2.

As noted, the look angle for a geosynchronous satellite here is
about 12 degrees if the satellite is directly south. What makes
you think there would be no earth reflections? In particular
for a satellite that is not directly south, and is, for example,
less than 6 degrees above the horizon?

Think that over in terms of the beamwidth (and side lobes too!)
on a 4 meter dish used for C band. And if you want a real excersize
in what is interesting, think about what that does in relationship
to sun outages...

>Terrestrial microwave paths are often designed to minimize earth
>reflection.

If you have obvious reflection points and/or knife edges
creating Fresnel zones, yes. But when you have two sites
sitting on mountain tops with a valley floor 6000 feet below
them, it may not be something you can calculate accurately.
Instead, with a long path, one has to design a system that can
be configured as needed... Perhaps, for example, by having 50
feet of vertical adjustment available for the antenna location.

>Reason is, on a long path, the lengths of the direct ray and the Earth

What does "on a long path" have to do with it? All that it
requires is that one path be a 1/2 wavelength longer than the
other path. Both can be quite short.

Where do you get off offering these never quite correct lectures
that never quite hit the point?

>The phase of the signal undergoes 180-degrees of phase change as we
>examine the signal either forward or backwards from the plane of the
>signal.

I think you can dispense with the lecture mode Richard, most 12
year olds that have knack for science can see that from looking
at what happens when rocks are tossed into a pond.

>That is to say, the phase of the signal is a function of
>distance along the path.

Actually it is a function of time, not distance. The same
distance could produce vastly different results.

>When a second signal source is created by Earth
>reflection on the path, the combination of the direct and reflected rays
>produces strata of stronger and weaker signal intensities as altitude
>changes. No reflected signal, no significant variation of signal with
>altitude, given sufficient path clearance. This is a worthwhile design
>goal.

Yes it is. Did you think anybody reading this thread did not
yet know that?

>No matter which end of the TV relay path was varied to produce a
>significant signal strength change, the attenuation at the higher
>elevation was probably caused by an Earth reflection. Another reflecting
>surface near the microwave path could have been the reflector. I`ve seen

However, as noted, this was a long path, with *extremely* high
elevations for both antennas. Think about it for awhile.

>that in the city canyons I`ve had to squeeze signals through. But on
>most paths, the Earth is the most likely reflector.

Somehow I suspect that for what was described, we can safely
ignore tall buildings as possible sources of reflections, don't
you think?

Interesting design on the last page of ARRL's Wire Antenna Classics. It's a coax fed monobander, made according to formula with 90 degrees between legs that are 1.25 WL long. As I recall, the feedpoint impedence is 100 ohms, so the designer connected a second vee in parallel back-to-back to get a 50 ohm feedpoint. One support mast 0.25 WL high. The elements end near ground level. By use of a single dpdt relay at the feedpoint the beam can be steered 90 degrees. It's bidirectional, so f/s is good but f/b is zero. I believe the designer described it as an "inside out rhombic."

It would be interesting to hear from anyone who has direct experience with this design.

I would like to build a 908Mhz turnstile.

How does one normally go about testing and adjusting an
antenna at that high of frequency?

For a lower frequency I can hook up a MFJ antenna analizer or an SWR
meter,.

I want to build a 900Mhz antenna with a hemispherical pattern.
It is going on an RC plane, so a normal vertical style antenna will
be problematic as it will have a null straight down.

So I though a turnstile antenna would be perfect.

Any advise on designing such a device?

Paul Kl7JG

1220. 50 Ohms "Real Resistive" impedance a Misnomer?

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-15 05:32:12 UTC
From: radio913@aol.com
Message-ID: <1d15af91.0307142132.772dc565@posting.google.com>
Source record: 112666

Hello,

I'd like to start a discussion (or light a brush-fire, as the case may be for this NG!), about what a 50 Ohm impedance match really means.

On our trusty Smith Chart, assuming it is normalized to 50 Ohms, the center is considered and labeled as the "real resistive" 50 match point. In fact, the entire middle horizontal line is the "real" part of the impedance.

I'm sure many of you have read the popular description/model of a transmission line as an infinite chain of alternating series inductors with shunt capacitors, with the resulting characteristic impedance as Z=(L/C)**1/2, where the L and C are distributed inductances and capacitances.

So, in theory, if you have achieved a perfect match with your antenna, you will have matched the impedance to the 377 Ohms of free space, you will not have reflections at the matching point, and the energy will radiate in whatever pattern you have designed for.

The funny thing about this, is that you cannot say that the 50 Ohms in the center of the chart is a "resistive" 50 Ohms, as there is very little real resistance in the average antenna. This "resistive" 50 Ohms is really what people call the "radiation" resistance, which is something of a misnomer again, because this is trying to equate the successful impedance matching and subsequent non-reflected EM radiation with a truly real resistance like an ideal dummy load.

Of course, it's well known that a truly real resistive 50 Ohm dummy load should appear exactly like a properly matched antenna to the transmitter.

Why do i ask all this? Well, if you believe that complex impedance measurements (series equivalent) by MFJ antenna analyzers are not completely inaccurate, then it appears that two 1/4 watt 100 Ohm resistors in parallel (lead lengths short) are a much more consistent 50 Ohms over the VHF band than almost all the higher power dummy loads we have tested.

Problem is, the high power dummy loads will vary from 52 to 45 "real" ohms depending on the frequency, with the "real" part of the impedance getting lower with increasing frequency, so it doesn't seem to be a "skin effect". The spread gets much worse when you put a 3' jumper coax in between, and even more worse when you add a power/swr meter. Then the "real" Ohms will be from 65 to 35 ohms, with the max

and mins not correlating with frequency at all, and the stray reactances will be much more too, but just as varied with frequency. So much for "50 ohm" jumper cables! I suppose they are as close as they can get them for a particular price.

My theory is that the "real" part of the impedance is mainly the truly resistive 50 ohms of the dummy load at low frequencies around 10 MHz or so...but as you go up in frequency, the parasitics of the dummy load and the coax jumper cable will cause "radiation" resistance to be mixed in with this truly real 50 ohms, giving us readings all over the map.

What do you folks think?

Dr. Slick

1221. 40 m inverted vee question?????

My 40 m reson. iv used to be completely horizontal at 30 ft.

I had to bend one end (while leaving the other horizontal) at
about a 45 deg angle to about 10 ft above the ground.

The SWR seems to be higher. 1.5:1 at its lowest. I can't remember
what it was before but I know it wasn't this high.

Will this cause an efficiency problem or any other?????

You might not, others would, and there is nothing "funny" going on in
the first place. As to "real" resistance, that is merely semantics
and does not illuminate just what you want to talk about.

>This "resistive"
>50 Ohms is really what people call the "radiation" resistance, which
>is something of a misnomer again,

It is only a misnomer that you brought to the table. There is, by and
large, no antenna that is by nature 50Ohms in the first place, but
there are many antennas that have been cobbled together to present
50Ohms - not the same thing; but also hardly distinctive either,
except to the semanticist. Radiation resistance is NOT a function of
drive point impedance even if the two share the same value for some
obscure design.

You have a lot of supposition going on to this point. Most of it is
more likely due to the difficulty of performing an accurate RF power
measurement in the first place.

Hi OM,

Theories abound and I have a 50Ohm dummy load that is fairly flat from
DC to 1GHz (confirmed by calibration to be less than 1:1.2 anywhere)
that I bought for $50. True, it is actually 52Ohms (the actual
standard of post WW2 Electronics), but its frequency characteristics
are just fine. More so than your experience in either obtaining
accuracy, or confirming it, or both.

How you make the leap to "radiation" resistance to make up the
difference in your observations is inventive, but not compelling; and
certainly lacks considerable discussion.

So, to respond directly to the subject:
>50 Ohms "Real Resistive" impedance a Misnomer?
Yes, as the nominative you employ.

The Select-A-Tenna tuning loop from C.Crane might help. Go to
http://www.ccrane.com/

They also sell the GE Super radio there.

You can also just call them -- they sorta specialize in long distance
AM listening.

No, an antenna doesn't "match" the impedance of free space. The input impedance of an antenna is the ratio of V to I. The impedance of free space is the ratio of the E field to the H field of a plane wave. They both happen to have units of ohms, but they're different things and there's no "matching" going on. If you apply 100 watts to an antenna, resonant or not, 100 watts will be radiated, less loss, regardless of the antenna's input impedance.

> The funny thing about this, is that you cannot say that the 50
> Ohms in the center of the chart is a "resistive" 50 Ohms, as there is
> very little real resistance in the average antenna.

Sure you can. You're confusing resistance with resistors. Resistance is a dimension, like length. There are lots of things which have dimensions of resistance but aren't resistors, like transresistance, characteristic resistance of a transmission line, or radiation resistance to name just a few. People who have a shaky understanding of basic electric circuit theory seem to have trouble dealing with this, but it becomes easier to deal with as you learn more about basic electricity. A mechanical example is torque and work, which have the same dimensions (force times distance) but are definitely different things.

This "resistive"
> 50 Ohms is really what people call the "radiation" resistance, which
> is something of a misnomer again, because this is trying to equate the
> successful impedance matching and subsequent non-reflected EM
> radiation with a truly real resistance like an ideal dummy load.

Sorry, that doesn't make a whole lot of sense. Yes, it's called the radiation resistance, but it's not a misnomer at all. (I suppose it would be if you called it a "radiation resistor", but nobody I know of has ever called it that.) If you calculate the power "consumed" by this resistance (that is, the power flow into it), it's the power being radiated. If the radiation and loss resistance of an antenna were zero, no energy would flow into it and consequently none would be radiated. (If the radiation resistance was zero and the loss resistance wasn't, then energy would flow into the antenna but none would be radiated -- it would all be dissipated as heat.)

Your use of "non-reflected EM radiation" seems to imply that the radiation from an antenna is somehow bounced back from space if the antenna feedpoint impedance is reactive. That's one of the rather bizarre and very wrong conclusions you could draw from the mistaken idea that the antenna "matched" the characteristic impedance of free space.

> Of course, it's well known that a truly real resistive 50 Ohm

No surprise. It's much harder to make something that's physically big have a consistent impedance at high frequencies than for something physically small, simply because stray inductances and capacitances are both larger for large objects. Let that be a lesson.

> Problem is, the high power dummy loads will vary from 52 to 45

> So much for "50 ohm" jumper cables! I suppose they are as close as
> they can get them for a particular price.

It's no trick at all to tranform a real resistance to a different value of real resistance using only purely reactive L and C components. It's

done all the time. An L network, with two components, is the simplest circuit which can pull off this magical trick. Just pick a point on the real axis of that Smith chart of yours and follow reactance lines around -- first XL, then XC, or vice-versa, until you end up back on the real axis again -- at a different resistance value. The amount of XL and XC you transit along the way are in fact the values you'd need to make an L network to do the transformation. As for the transmission line, start at, say, 45 ohms, then go in a circle around the center, reading off R and X values as you go. Those are the values of R and X you can get with a 50 ohm transmission terminated with a 45 + j0 ohm load. Of course, "50 ohm" lines are often quite a ways off -- I've measured them at up to 62 ohms or so. And you're right, you can get better ones if it's worth a lot to you. Oh, also notice that if you start on the real axis anywhere but the center and go around a half circle, representing 90 degrees of lossless transmission line, you end up at a different place on the real axis. Presto! You've pulled off a transformation of a purely real impedance with a lossless transmission line. Cool, huh?

> My theory is that the "real" part of the impedance is mainly the

> map.

Although radiation will cause an increase in terminal resistance (remember, it accounts for the radiated power), it's not at all necessary in order to cause the dummy load resistance (real part of the impedance) to vary. The stray L and C can do that all by themselves, without any radiation at all.

>
> What do you folks think?
>

I think you'd benefit a lot from learning how to do some basic operations with a Smith chart. It would broaden your horizons a lot.

From the IEEE Dictionary: "resistance (1)(B) The real part of impedance."

Apparently, all the resistance in the average antenna is real. :-)

Richard, thanks for the reminder.

Yes, the Beverage and other long-wire terminated antennas, although having lots of L and C, exhibit (ideally) no signs of resonance yet have purely constant vs frequency resistive feedpoint impedances.

They are all transmission lines which radiate because the spacing between conductors is an appreciable fraction, or more, of a wavelength, one of the conductors being whatever the local environment consists of.

Their equivalent lumped circuit networks come under a class of 'constant-resistance' networks commonly found in design of filters and equalisers.

The most simple example of a constant-resistance network is a capacitor in series with a resistor, both in parallel with an inductor in series with a resistor. When all 4 components have the same value in ohms (R) then the input resistance is a constant resistance R from DC to infinity.

I disagree on this point. You can think of an antenna as a type
of tranformer, from 50 Ohms to 377 Ohms of free space. A tuned
antenna is "matching" 50 to 377 ohms, and will therefore have no
reflections, ideally.

Have you heard of something called mis-match loss? If the
antenna's input impedance is not matched to the tranmission line (or
the final PA), then the radiated power will be significantly less than
100 watts.

ok, so perhaps the way to think of it is: when an antenna is
matched, the I and V curves will be in phase (no reactance), and the
product of I*V (integrated) will be the power transmitted.

If both the radiation and loss resistance were zero, i would
expect an ideal short, and therefore full -180 degree reflections.

I suppose what this all means is that if you have a matched
antenna, it's V and I curves will be IN PHASE and will have the exact
same RMS values as if you had a truly resistive dummy load instead.
Therefore, you can consider the center of the Smith Chart (or the
entire real (non-reactive) impedance line) as a real resistance like
an ideal dummy load.

Do you agree with this statement Roy?

I suspect that there is plenty of series inductance and chunt
capacitance in our dummy loads, so that especially at higher
frequencies, the starting point is anything but a perfect 50 ohms.
Hence the transformation with the 3' coax.

Ok, you make sense on this point. The readings all over the map
can be due to not starting at the center of the chart(see above), and
also imperfect 50 ohm coax. So I agree radiation resistance is not
necessary, but i suspect it may have a role in this case.

>
> I think you'd benefit a lot from learning how to do some basic

I believe i understand the Chart better than you think, Roy,
enough to know that you do know what you are talking about.

I still think it's ok to consider antennas as impedance
tranformers, but you have brought up some very good points.

Thanks for the input.

Guys,

While I appreciate the banter, and the points supposedly being made,
might I ask if anyone has an actual answer to my original question?
All I want to do is feed a dipole or longwire without running 250 feet
of ladder line across the yard, so I can cut down on my antenna farm
(Dipoles, etc, all strung up from the trees). A tuner out in the yard
seems like a reasonable solution.

Thanks in advance.

SGC has a 500W autotuner. You might contact them and ask how much power
it will handle if it was first tuned using 500W and then the power
increased to ______.

Not if there's an antenna tuner (Z0-match) in the circuit. The
following will radiate most of the mismatch loss from the load.

100W XMTR--50 ohm feedline--+--1/2WL 150 ohm feedline--50 ohm load

All of the reflected energy is re-routed back toward the load at
the '+' Z0-match point through re-reflection and wave cancellation.

Tony,

Adding more elements seems like the only practical solution. You would probably have to add 6 -8 feet to the boom, and 2 more elements. Keep in mind the longest element will be about 38 feet long. That is why they make the 18 -30 MHz version. BTW, Tennadyne used to make an 18 -30, but I don't see that listed on their web site any more. You might want to check them out anyhow for any ideas.

Source record: 112584

Floyd Davidson wrote:
"---the look angle for a geosynchronous satellite here is about 12 degrees if the satellite is directly south."

Floyd is in Alaska. Floyd`s example of anomalous propagation from reflection to a terrestial transmission was in Arizona. On the equator, the "look angle" may be nearly straight up.

The reason a satellite dish is less susceptible to earth reflections is that the satellite dish is not aimed to pick the reflections up. The satellite dish is aimed at the sky.

A terrestrial microwave dish aimed directly at the satellite dish is likely not transmitting an interfering frequency, but if so, it is unlikely to be aligned well enough or above the horizon of the satellite dish.

The approximate specifications of a 6-foot dish for beamwidth and gain versus frequency are:

1.3 GHz 9 deg. 25 dbi

2.3 GHz 5 deg. 30 dbi

3.5 GHz 4 deg. 33 dbi

6 GHz 2 deg. 36 dbi

10 GHz 1.5 deg 43 dbi

25 GHz 0.5 deg 50 dbi

Sources of the above are the "RSGB VHF-UHF Manual" and the ARRL Antenna book (they agree).

In moderate latitudes, the satellite earth station antenna is really looking up. It is quite likely terrestrial signals are not within range of its bandwidth, beamwidth, or distance.

Best regards, Richard Harrison, KB5WZI

Since the reactive components change reactance with frequency, Reg's network
may be a little hard to realize in practice. Try making the inductance equal
to
R^2*C Reg. You might have better luck. You also might want to review
Everitt's
take on this subject, starting on page 284 of the second edition of his book,
Communication Engineering. His ideas are quite enlightening.

Slick,
You're not going to make many points on this or any other newsgroup just by
using rudeness as an argument. You need to read more books, Slick, so
you'll have more to add to a discussion than an attitude. You should also read

Richard's posts very carefully and try to figure out what he's saying before
you
fly off the handle and assume the attitude of an angry, petulant child. You'll
learn something and possibly avoid being made a fool of by some of the more
technically sophisticated members of this newsgroup.

>
>Dale

Hi Dale,

Graphics straight from EZNEC which has served this group for years.
Select any graphic and simply ask the browser to view that page. If
you are unfamiliar with the drawing conventions I would suggest
getting the free version and becoming adept. The SWR drawings show 40
data points quite clearly between 440 and 460 (every 0.5MHz) no more
resolution is required, there are no surprise resonances hidden
between data points.

This is a very simple antenna, the description of the main radiator:
"This is a low, long antenna roughly quarter wavelength from the
ground point, up to the bend, out to the end. The drive point was
found by trial and error."
is quite explicit but I already admit may be confusing, thus the
attending illustration. There is only one ground, there is only one
bend, there is only one feed. The name describes it as well:
"Inverted F" The letter F certainly is descriptive. The only
embellishment is that it is constructed with a sheet rather than a
wire, but both sheet and wire models' SWR are also shown and
discussed:
"Because of the sheet metal form, this qualifies as a thick
radiator. The SWR curve on the left confirms this when compared to
the SWR curve below."
"This is the SWR curve for a one wire model of the design modeled
here."

The design couldn't be simpler for those already adept at building
grounded verticals with a gamma feed - and without the cap of the
gamma feed. The vertical is simply folded over at the feed.

Source record: 112588

Dr. Slick wrote:
"The funny thing about this is that you cannot say that the 50 ohms in the center of the chart is a "resistive" 50 ohms as there is very little real resistance in the average antenna."

Resistance is defined as real. That is, current is instantaneously proportional to the voltage.

Any efficient antenna has a high ratio of radiation resistance to loss resistance.

Resistance is the ratio of in-phase voltage to current accepted by an antenna. Part is made by loss in the antenna. part is made by radiation from the antenna. They are often represented by an equivalent circuit of two resistors in series.

Dr, Frederick Emmons Terman says of radiation resistance:
"This is the resistance that, when inserted in series with the antenna, will consume the same amount of power as is actually radiated. ---it is customary to refer the radiation resistance to a current maximum in the case of an ungrounded antenna, and to the base of the antenna when the antenna is grounded."

Best regards, Richard Harrison, KB5WZI

>The reason a satellite dish is less susceptible to earth reflections is
>that the satellite dish is not aimed to pick the reflections up. The
>satellite dish is aimed at the sky.

The reason your example is poor is that it assumes something
which *clearly* is not always true. Satellite dish antennas are
not always aimed significantly far away from the earth's
surface.

>A terrestrial microwave dish aimed directly at the satellite dish is
>likely not transmitting an interfering frequency, but if so, it is
>unlikely to be aligned well enough or above the horizon of the satellite
>dish.

That is not necessarily true. And in fact I've seen 4 gig
terrestrial microwave systems cause grievous interference to
satellite systems. (In one case, by reflections off a metal
building across the street from the satellite dish, which caused
the weird effect of the interference coming from a microwave
that was 20 miles distant directly *behind* the direction the
satellite dish was pointed!).

>The approximate specifications of a 6-foot dish for beamwidth and gain
>versus frequency are:

This doesn't account for side lobes, and hence gives a *very* false
indication of the actual susceptibility to interference arriving at
angles off the main lobe.

>
>In moderate latitudes, the satellite earth station antenna is really
>looking up. It is quite likely terrestrial signals are not within range
>of its bandwidth, beamwidth, or distance.

But not all microwave systems requiring path engineering are
located so convenient for your specifications. It is simply false
to claim that, even at moderate latitudes, the satellite antenna
is *necessarily* looking at a high angle above the terrain. Locations
with small latitudes *can* see some satellites at high angles, while
locations at high latitudes *never* see a geosynchronous satellite
at a high angle. But in either case there are *many* satellites
at lower angles.

My understanding of that setup is that the two cophased whips need to
be a quarter wavelength apart in order for it to work properly,
although I may have been misinformed.

However, if this is correct, it's gonna be tough to find a vehicle
that will let you separate two cophased whips by a quarter wavelength
at 80 meters - and driving it down most city streets would probably be
quite an experience even if you could find one that large. (Maybe the
tractor that moves the space shuttle from the vehicle assembly
building to the launch pad...top speed is slower than most folks can
walk, though)

Thanks but no thanks, OM. You certainly have a crappy dummy load you
may have confirmed through haphazard testing that you then rejected
with opinion and speculative theory. That quality was evident
throughout.

You also have a low threshold for your avowed mission to
>light a brush-fire
As always, you have complete control in what you choose to write, and
you chose opinion over technical discussion. As far as opinion or
brush fires goes, you don't seem well suited for that either.

Hi Richard,

This is seems to be a point of convergence for the derivation of many
fascinating and strange theories of fancy and speculation.

You point out in the remainder of your posting about the combination
of resistances (giving particular care to describe in terms of phase)
and yet many posters here fail to account for those same assortment of
R's available from real life.

One notable offering of measuring antenna (or load) impedance involved
the use of a thermometer to which I asked "what is the Z for a 1
degree rise?" I was not surprised to find no answer forthcoming even
when the premise was sound. Such is the shortfall of speculation in
the face of analytical enquiry. There is no corresponding shortfall
of opinion draped in the mantle of citations unfortunately.

These attempts to separate "real" resistance from other resistances
are challenged with volumes of formulaic recitation, and the absolute
resistance (yet another meaning) to merely stepping out into the field
with an OhmMeter (much less that same thermometer). Clearly,
resolution of these imponderables is not a target for some scribblers.

For many years there has been this effete distinction of there being
dissipative and non dissipative resistance (perhaps the basic, or
elemental concern of this thread; yet through hazy writing that agenda
remains elusive). The transmitter cannot possibly separate the two.
It thus remains for the target audience to resolve, but even they
cannot either unless the incident of gaining or losing this additional
resistance occurs in a short enough interval to allow its perception
(notably expressed in dB). If the researchers refuse to do some field
work, it will always remain among their mysteries of the sacrament.

Hi Paul,

Total radiator length (M) is ï¿½ wavelength (approx).

Use the drawing (viewed as its own page) to print a copy and scale all dimensions by wavelength. Do not presume any correction factors, simply use one Meter to be one Meter (not 0.95 Meter) at one Meter wavelength. I deliberately left the segments visible to aid in scaling. You should be able to perceive that the structure folds at roughly 0.04 wavelength, which is also the height above the ground plane. The foreshortened width of the sheet metal is also on the scale of 0.04 wavelength.

For your application at 900MHz be aware that even thin wire (as in the feed) becomes significantly thick enough to change resonance and feed resistance through slight geometrical variations. This is true for any construction. That is why I provided the caution that it was chosen (or discovered) by trial and error. Given the 10MHz wide 2:1 BW, discovery covers a lot of turf. By purposely using thick components, this becomes less an issue. At these very short wavelengths, it is a rather simple matter to build deliberately wide resonant (low Q) structures.

Hi Capo:

The Z of an antenna changes with its height above ground. It is not a liner function but follows a curve. There is a chart in all antenna handbooks showing the change with height above ground. Anyway you lowered the average height of your antenna so you changed the Z of the antenna. Lowering the antenna will change the shape of the radiation pattern. It will not change the efficiency of the antenna, if you put a 100 watts in it will radiate 100 watts.

> What do you folks think?

With just a bit of experience in this area, I think you need to find a
way to control your experiments more carefully so you KNOW what's
going on, to a better approximation. I'm quite sure it's possible to
build fairly high power dummy loads--at least high enough power to
handle legal amateur transmitter outputs--that present much better
matches than you describe. Our most usual problem in calibrating
precision instruments at high frequencies is in finding cables which
are really close to 50 ohms and are also practical for routine tests.
Some of the other parts such as power splitters present problems, too.
But we've gotten pretty good at figuring out just where the errors
creep in, through a combination of analysis and experiments. For
sure, our work builds on a tremendous amount of work that has gone on

in the past in the area of precision RF measurements. We currently work at frequencies from DC to several GHz, and worry in the GHz range about errors equivalent to an ohm or so...less down at 100MHz and below.

But for ham applications, do you really care about all this? There's probably not a need to, if you're just trying to get power to an antenna, but if you care because you simply want to learn how to build a precision system and make precision measurements, that's fine too. You should be able to find lots of info on the web about that...try, for example, to find Hewlett-Packard/Agilent ap notes on RF measurements and calibrations.

Cheers,
Tom

1253. Shielded Loop - Velocity Factor?

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-15 18:13:50 UTC
From: Loopfan <bgreer1@earthlink.net>
Message-ID: <yvXQa.102379$lo.8784543@newsread2.prod.itd.earthlink.net>
Source record: 112596

I have a few more questions, but first I'd like to thank everyone for their feedback. After doing some usenet searching, it seems that I am retracing the footsteps of those from about 1995 onwards. I'd like to thank W7EL, W8JI and others for making my head hurt. <grin> I feel like that character in Close Encounters making a mash-potato mountain in his living room....

I have been cutting my coax loops to less than 1/10th of a wavelength and also taking the velocity factor of the cable into account. After your help with analyzing transmission lines, and proving for myself that the outside shield is the antenna by way way of being able to attenuate it with an RF choke, I am now wondering if I should *NOT* take the velocity factor into account and make my loops with disregard to the velocity factor? Or does the jacket contribute to the velocity factor of the outer-surface of the cable?

Question 2: Have we come to any conclusions about how the current gets from the outer-skin surface of the shield to the inner-skin surface of the shield? I don't want to rehash an old topic, so I'll be just as happy to say that it merely *does*. I'm wondering if there is a field set up on the outer skin edge that encompasses the inner-skin edge and transfers current that way, or can I view the inner and outer skins as more or less the same conductive skin surface that has a 180 degree bend in it so that its analogous to the inside and outside being the same sort of "outer" skin? Looks like I'm confusing myself...

I'll be happy to do more usenet message searches if that will prevent a total flareup of the same old topic.

Thanks and 73
Brian

Thinking of it doesn't make it so. All the energy applied to the antenna
is radiated, less loss, regardless of the antenna's feedpoint impedance.
How does that fit into your model.

The average power radiated is always the real part of V*I(conjugate). If
V and I are in phase, this is simply equal to V*I. But what does this
have to do with the confusion between a resistor and resistance?

You're assuming that the antenna is fed with a transmission line, but
that's ok.
>
> I suppose what this all means is that if you have a matched
> antenna, it's V and I curves

what curves?

will be IN PHASE and will have the exact
> same RMS values as if you had a truly resistive dummy load instead.

Yes and no. If you're feeding the antenna with a 450 ohm line, it's
matched to the line only if its impedance is 450 + j0 ohms, so it looks
like a 450 ohm dummy load, not a 50 ohm one. On the other hand, you can
feed a 50 + j0 ohm antenna with a half wavelength of 450 ohm line, and
get a perfect 50 ohm match to a transmitter at the input end of the
line, while running a 9:1 SWR on the the transmission line. Then either
the antenna or the input of the line looks like a 50 ohm dummy load.

> Therefore, you can consider the center of the Smith Chart (or the

> 50 Ohms to 377 Ohms.

I like to think of 'em as sort of potato guns, launching RF potato
photons into the aether. But that doesn't make them potato guns.

Feel free to think of them any way you like, as long as you consistently
get the right answer.

Now tell me, why can't you just make some 377 ohm transmission line
(easy to make) open circuited, and dispense with the antenna altogether?

When you figure out the answer to that one, you might begin to see the
error with your mental model.

==========

Tom, sorry to be so disappointing. My Little formula for calculating L and C for the constant resistance network is quite correct.

When designing constant-resistance networks it is convenient to have a design-frequency.

It can be the frequency at which I said Xc = Xl = R ohms.

So we can now calculate both L and C without prior knowledge of either of them. After a little arithmetic it will be quite enlightening to discover , as you say, that L = C*R^2, but which is a less-convenient starting point.

In addition to a design frequency there can also be a design time constant.

Reg, G4FGQ

> of the outer-surface of the cable?

The transmission line velocity factor applies only to the inside of the coax, where the fields are entirely within the dielectric material. Waves on the outside of the shield are propagating at nearly the speed of light. A jacket will slow propagation by somewhere around 2 - 3%.

It's not apparent why you need to worry about the exact electrical size of the loop anyway, unless you're trying to predict with good accuracy how much tuning C you'll need.

> Question 2: Have we come to any conclusions about how the current gets
> from the outer-skin surface of the shield to the inner-skin surface of

Sure. It flows from the outside to inside at the gap, around the cut edges of the shield.

I don't want to rehash an old topic, so I'll be just as
> happy to say that it merely *does*. I'm wondering if there is a field

> sort of "outer" skin? Looks like I'm confusing myself...

Actually, you're pretty close. The current simply flows around the edge. It might help to visualize the shield as being hollow, with a separate inner and outer "shell", connected only at the cut end of the gap. That's what it looks like to the RF. The field on the outside of the shield doesn't penetrate the shield, nor does the field on the inside. So the two have no effect on each other -- except at the gap. The current gets from one surface to the other purely by conduction.

Considering some of the patents that have been issued, like for the "Faster than light antenna", it wouldn't surprise me. But it's too late to apply now if it hasn't already been done. I proposed this in a posting a few years ago. April 1, I believe it was. The one year limit following public disclosure has long passed.

So it's public domain, guys! Experiment away! Cut down your beams and all those other unnecessary, inefficient "matching" devices, and feed the aether direct!

>C for the constant resistance network is quite correct.

Yes, of course, but misleading because it implies that all four components have to have the "same value in ohms (R)." In fact, the input resistance will be the same no matter what the value of the reactive components as long as they obey the requirement that L/C = R^2.

>

I wonder if radiated energy would increase measureably if one were to try to balance mobile whip antenna by having another whip connected directly to the body and tuning it. If it would, how would one locate, size, and tune it?
tnx

You misunderstand my point, Cecil.

If the antenna is tuned correctly, the "radiation" resistance is a
real 50 Ohms, with the V and I waveforms IN PHASE. But, my point is
that you can take a DC measurement anywhere on the ideal lossless
antenna and you will never see 50 Ohms anywhere, only shorts.

Ideally, the antenna never heats up, and has no resistive losses.
This is not to say that it won't have a "radiation" resistance of 50
Ohms at the resonant, tuned frequency. And to a transmitter at the
resonant frequency, this will electrically appear to be the same thing
as an ideal dummy load of 50 Ohms.

Roy's message has clarified a few things.

Hi Hank,

The body is already the balancing whip you propose. Your addition
would be like adding a thin radial to an already massive one (like the
needle on a cactus).

Actually, what most Hams consider to be their antenna, it is actually
a tuned radial to the larger radiating frame. There is little
distinction between such primitive elements at large wavelengths if
you are talking about 80M or so. Some would argue that their
screwdriver elongates the current loop (the indicator of gain against
the overwhelming short dimensions) to qualify it as radiator, that is
simply a trick of symmetry and their being able to tune a thin element
instead of the more massive one (unless they drive a variable-stretch
limo).

Why would you need the antenna tuner in this case? Assuming your
XMTR is 50 Ohms on the output:

> 100W XMTR--50 ohm feedline--+---50 ohm load

Voila! A perfect match. No mis-matchlosses, and no need for a
tuner.

Yes, but a real-world antenna rarely has a 50 ohm feedpoint impedance
even though it is resonant. The feedpoint resistance of a resonant
1/2WL dipole can vary from about 40 ohms to about 100 ohms depending
upon its height above ground. And a resonant dipole won't usually
cover the entire 75m band without a tuner of some kind.

> of the outer-surface of the cable?

Since you're making the loop small compared with a wavelength anyway,
just how does it matter? I would think the difference in feedpoint
impedance (the gap) between jacketed and unjacketed line would be very
small indeed.
>
> Question 2: Have we come to any conclusions about how the current gets
> from the outer-skin surface of the shield to the inner-skin surface of

> more or less the same conductive skin surface that has a 180 degree bend
> in it so that its analogous to the inside and outside being the same
> sort of "outer" skin? Looks like I'm confusing myself...

So one way to make the loop, assuming the gap is at the top, is to
make one side out of coax (which becomes the feedline) and the other
side out of solid rod the same OD as the feedline. Attach the center
conductor of the feedline where it comes out at the gap across the
gap to the center of the solid face of the other side. Equivalently,
make both sides out of coax, but put a shorting disc from outer to
center where the center re-enters the coax after the gap. Now it's
easy to see that the voltage across the gap is simply the voltage
delivered to the feedline.

It's true that whatever current is on the outside of the outer
conductor right at the gap must be balanced by a current on the inside

of the outer conductor on the coax side. Otherwise, charge would pile up at the gap. And on the side with the shorting disc or solid conductor, the current on the outside of the conductor must be balanced by a current in the disk and practically by the same current delivered to the inner conductor of the coax where it attaches to the disk. Again, if it didn't, charge would pile up there. It's OK to pile up a little charge if there's a capacitance to put it on, but in a very small volume, there can't be much capacitance.

Remember, too, that the current is there (in a receiving antenna) because we put a load across the gap by means of the coax feedline. Otherwise, any current would only be there to charge the capacitance of the gap (to a voltage corresponding to the EMF given by Faraday's law, less a tiny I*R drop in the conductor).

Cheers,
Tom

But where does that 33.33 watts actually go? If you have 100 watts coming from the source, and 100 watts traversing the first and second boundaries, where does the 33.33 watts go?

No, no, no. Different principle entirely. He's talking about using the second whip connected directly to the body of the vehicle - in effect using it for the missing half of the dipole.

This has been done in the past by a number of folks and they seemed to like it. Whether it is worth the trouble is questionable. Give it a try and let us know how it works out.

1277. Re: 50 Ohms "Real Resistive" impedance a Misnomer?

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-16 01:37:32 UTC
From: richardharrison@webtv.net
Message-ID: <15368-3F14AC5C-413@storefull-2313.public.lawson.webtv.net>
Source record: 112521

Dr. Slick wrote:
"But, my point is that you can take a DC measurement anywhere on the ideal lossless antenna and you will never see 50 Ohms anywhere, only shorts."

True. D-C resistance of a lossless wire is zero. But, apply 50 watts r-f power to an antenna adjusted to present 50-ohms resistance at a particular frequency.

What happens? Our loading, adjusted for 50 watts output, produces 50 volts at an in-phase current of 50 amps.

The 50 watts is being radiated. As far as the transmitter is concerned, the power might just as well be feeding a dummy load.

There are several reasons a d-c ohmmeter doesn`t read radiation resistance. Once the ohmmeter`s d-c has charged the antenna, current flow stops. D-C doesn`t radiate. A d-c ohmmeter doesn`t even measure the right loss resistance value. Some of the loss resistance in a true antenna with actual losses, comes from skin effect at radio frequencies, where the conduction is forced to the outside of the conductors, decreasing their effective cross-section and increasing their loss. R-F also has the ability to induce eddy currents in surrounding conductors and to agitate molecular movement in surrounding insulators. R-F thus increases loss over that measured by passing d-c through the antenna.

Radiation resistance can be readily measured by using an r-f bridge instrument. The bridge and antenna are excited by a generator operating at the same frequency the transmitter will use. The bridge will indicate reactance in the antenna, if it is not resonant. The null detector for the bridge is typically a good radio receiver.

Radiation resistance is real though it does not heat the antenna. Loss resistance is real though it does heat the antenna and its surroundings.

A resistance is a volt to amp ratio in which amps are in-phase with the volts.

A resistor is a special type of resistance in which the electrical energy applied to the resistance is converted into heat.

Best regards, Richard Harrison, KB5WZI

1278. efficiency of horizontal vs vertical antennas

From: Ron <rmrippy@hotmail.com>
Message-ID: <o02Ra.290594$jp.7848137@twister.southeast.rr.com>
Source record: 112520

There doesn't appear to be any ground loss resistance in horizontal antennas (e.g., dipoles) such as there is in verticals. Does this mean that verticals are virtually always less efficient than horizontals due to their ground loss?

Ron

1279. Re: efficiency of horizontal vs vertical antennas

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-16 02:00:48 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <vh9ceshoh40s6d@corp.supernews.com>
Source record: 112522

A vertical dipole, or a base fed half wave vertical, has good efficiency and no significant ground loss. That is, there's no appreciable loss from current flowing through the ground to a feedline terminal. For other verticals, such as a base fed quarter wavelength, ground loss due to return currents can be reduced to an arbitrarily low value by using a good enough system of radials.

However, after the wave is launched from the antenna, vertically polarized signals react differently than horizontally polarized ones when they strike the ground. Horizontally polarized waves are reflected with little loss, except ones at high angles. With vertically polarized waves, it's the low angle ones that take the greatest beating. And since most vertical antennas tend to concentrate radiation at low angles, a very sizable fraction of the total radiated power is often lost in the ground reflection. This mostly takes place well beyond a reasonably sized radial field, so radials don't help. The only way to reduce this loss is to see that the reflection takes place from highly conductive ground, like sea water(*). Otherwise, you lose most of the power that you want the most.

(*) The effective conductivity of the ground improves as frequency decreases. So verticals tend to do better at lower frequencies, and often outperform horizontal dipoles on 160 and 80 meters, even over average ground.

Roy Lewallen, W7EL

Floyd Davidson wrote:
"And darned if a few years later a build up of rhime ice on the 43 feet of tower above the dish didn`t fall down and bend that dish into a pile of rubble too,"

By Floyd`s logic the lesson must be that a dish must always top the tower, out of harms way.

The antenna does not have to receive zero interference, though that would be nice. We are always susceptible to some interference from somewhere at some time. Multiphop systems often must reuse just a few frequency pairs over and over. It`s all the regulators will allow. Situations arise when anomalous propagation provides strong signals at extraordinary distances.

Planning includes avoiding azimuths which would repeat to present interference at a great distance along with a repetition of a frequency which might interfere. A solution to interference is coordination. Another is often high performance dishes which do a better job of rejection. I`ve used the shielded variety from Antennas For Communications (AFC) with good success.

Ice may be falling, but the sky isn`t in the case of microwave interference.

Richard, stop being an ass. Nothing that I've said suggested
any such stupidity, yet you frivolous and insulting.

>The antenna does not have to receive zero interference, though that
>would be nice. We are always susceptible to some interference from
>somewhere at some time.

So you finally got my point! It *is* going to have variations,
and those variations are *not* something you will likely
calculate to with the 1 dB you claimed to do _every_ _single_
time.

>Multiphop systems often must reuse just a few
>frequency pairs over and over. It`s all the regulators will allow.
>Situations arise when anomalous propagation provides strong signals at
>extraordinary distances.

More frivolous commentary that has nothing to do with the topic
of discussion. What is your point?

>Planning includes avoiding azimuths which would repeat to present
>interference at a great distance along with a repetition of a frequency
>which might interfere. A solution to interference is coordination.

Coordination is not optional. You cannot get a station license
without it.

>Another is often high performance dishes which do a better job of
>rejection. I`ve used the shielded variety from Antennas For
>Communications (AFC) with good success.
>
>Ice may be falling, but the sky isn`t in the case of microwave
>interference.

The only sky falling is your claims that you calculate path
losses to within 1 dB for *every single* microwave shot. It
just doesn't work that way Richard, and you are either 1) not
doing many path calculations, or 2) are forgetting about the

ones had some anomolous differences causing unexpected results.

Perhaps 98% of all microwave paths work out just about as expected,
but the other 2% are really interesting and sometimes we never do
figure out exactly what is causing the difference between calculated
and actual results. Any path over tidal water comes to mind... :-)

Jim Kelley wrote:
> But where does that 33.33 watts actually go? If you have 100 watts
> coming from the source, and 100 watts traversing the first and second
> boundaries, where does the 33.33 watts go?

Through a two step process, it merges in phase with the forward wave at the Z0-match point. A directional wattmeter reads 133.33W forward power. 100W + 33.33W = 133.33W. 100W/|1-rho|^2 = 133.33W
Forward power - reflected power = power delivered to the load.
The standing waves confirm that there is indeed 133.33W forward and 33.33W reflected.

Let's look at the following system with two sources. Each source is a signal generator equipped with a circulator and load. SGCL1 is equipped with a 50 ohm circulator and load and SGCL2 is equipped with a 150 ohm circulator and load. The two signal generators are phase locked but can be turned on and off independently.

rho=0.5
100W SGCL1---50 ohm feedline---+---150 ohm feedline---33.33W SGCL2
Pfwd1--> Pfwd2-->
<--Pref1 <--Pref2

Using the principle of superposition: With SGCL1 on and SGCL2 off, Pfwd1=100W, Pref1=25W, Pfwd2=75W, and Pref2=0W. SGCL2 dissipates 75W (Pfwd1)(|rho|^2) and SGCL1 dissipates 25W (Pfwd1)(1-|rho|^2). This is how the s11 and s21 s-parameters are measured.

With SGCL2 on and SGCL1 off, Pfwd1=0W, Pref1=25W, Pfwd2=8.33W, Pref2=33.33W. SGCL2 dissipates 8.33W (Pref2)(|rho|^2) and SGCL1 dissipates 25W (Pref2)(1-|rho|^2). This is how the s12 and s22 s-parameters are measured.

Note that SGCL1 dissipates 25W in both of the above cases.

With SGCL1 and SGCL2 both on, Pfwd1=100W, Pref1=0W, Pfwd2=133.33W, and Pref2=33.33W. This is similar to the earlier single source example. Note that the two 25W waves obviously engage in wave cancellation and their combined 50W of destructive interference joins the forward wave as constructive interference. Assume there is a set of feedline lengths that will accomplish the given values. Vref2 must be 180 degrees out of phase with Vfwd1 at the impedance discontinuity. I think 1WL of 50 ohm feedline and 1/2WL of 150 ohm feedline will do that if the voltages from the two sources are max+ at the same time.

b1 = s11*a1 + s12*a2 = 0V s11*a1 and s12*a2 engage in destructive interference.

Pref1 = Pfwd1(|rho|^2) + Pref2(1-|rho|^2) - destructive interference
0W = 25W + 25W - 50W

Pfwd2 = Pfwd1(1-|rho|^2) + Pref2(|rho|^2) + constructive interference
133.33W = 75W + 8.33W = 50W

Well, maybe yes and no. I think I heard that it is called "series tuning".
Now you would have to
mount the things on opposite ends of the car. Whether there is anything to
be gained, I haven't
tested it. It eliminates the matching network, tho. Heck, I've got enough
antennas on my car
without that.

I was thinking it was simply a resonant 1/4WL director or reflector
which would be very lossy on 75m.

What if the antenna was a wire shorting the transmission line?
Then there would be very little radiated power, and a lot of reflected
power.

You can make a transformer to match 50 Ohms to, say, 200 Ohms or
so. Why not for 50 to 377? It's just another number.

Except in the case of free space, with a given permeability and
permittivity, you have the impedance of free space, which doesn't need
a transmission line.

> >
> > ok, so perhaps the way to think of it is: when an antenna is

Well, a carrier with a single frequency will be a sinewave,
correct? Feeding a real resistive impedance, the V and the I
sinewaves will be in phase (no reactance).

It doesn't really, but it does relate to this discussion. In the
sense that V and I will be in phase for either a matched antenna or an
ideal dummy load.

> >

> the antenna or the input of the line looks like a 50 ohm dummy load.
>

You could make that half wavelength transmission line almost any
other characteristic impedance, like 25 or 200 Ohms, and you would
still wind up back at 50 Ohms at the input of the line (but you
couldn't change frequencies unless they were multiples of 2 of the
fundamental).

But the point is, you will still be at 50 Ohms at the input, so
the V and I sinewaves should be in phase.

> > Therefore, you can consider the center of the Smith Chart (or the

Cool. But a network analyzer looking into a black box will not
be able to tell you whether the 50 Ohms it is reading is radiated
resistance or dissipated resistance. This seems to be the crux of my
question.

>
> Now tell me, why can't you just make some 377 ohm transmission line

>
> Roy Lewallen, W7EL

Why would you need a 377 Ohm feedline for free space, when free
space itself is the transmission line??

What's wrong with thinking of an antenna as a type of series Inductor, with a distributed shunt capacitance, that can be thought of as a type of distributed "L" matching network that transforms from 50 Ohms to 377?

This is related to how you need to bend the ground radials of a 1/4 WL vertical whip at 45 deg angles down, to get the input impedance closer to 50 Ohms (as opposed to 36 Ohms or something like that if you leave them horizontal).

Slick

When you are trying to design a 9 element Chebychev low-pass
filter, it becomes important to test it will a 50 Ohm dummy load that
doesn't drift all over the place at higher frequencies.

Ok, i stand partially corrected. I should have stated this:

"You cannot tell if the 50 Ohms reading on a Network analyzer into
a Black Box is a dissipative resistance like a dummy load, or if it is
a radiated resistance of a perfectly matched antenna. You don't have
that information."

Richard, I like your definition of real: "Resistance is defined
as real. That is, current is instantaneously proportional to the
voltage."

In other words, the V and I sine waves will be IN PHASE.

This clarifies it more for me. BOTH the radiation resistance and
the dissipative resistance of a dummy load are both "real" resistive
impedances.

Thanks,

Slick

Great. Makes sense now.

> It's not apparent why you need to worry about the exact electrical size
> of the loop anyway, unless you're trying to predict with good accuracy
> how much tuning C you'll need.

Well, I was thinking about trying to maximize the area surrounded by the loop up to about 1/10th of a wavelength or so. What I found was that the distributed capacitance of my cable at this length was too much for my tuner to handle. So when I multiplied this length by my cable's velocity factor, 0.66, suddenly the tuner could handle it and the loop came alive! THIS is what got me on the wrong path thinking that the center conductor was the antenna, and that I had discovered some overlooked secret about the velocity factor. I was obviously mistaken.

> Actually, you're pretty close. The current simply flows around the edge.
> It might help to visualize the shield as being hollow, with a separate
> inner and outer "shell", connected only at the cut end of the gap.

Right. Kind of like a hollow knife blade. You've got two physical sides that meet at a cutting edge, but if you examine it closely, you'll see that we are only really dealing with one outer conductive surface "folded" so to speak back on itself. The edges of the exposed gap wires represent the cutting edge - a small distance to be sure, but it is a length of conductive material making a seamless join. Two sides, but one surface.

Thanks again for the help.

Hello Tom!

> Since you're making the loop small compared with a wavelength anyway,
> just how does it matter? I would think the difference in feedpoint
> impedance (the gap) between jacketed and unjacketed line would be very
> small indeed.

I was just trying to follow the mantra of trying to enclose as much area as possible. I found that in the end it wasn't as critical as I thought, ie changing a 10-foot circumference loop to 7-feet. As long as I could get my tuner to handle it, it seemed that the Q of the circuit made up for the small difference in the loss of the capture area. So in the end, you are right, the difference in feedpoint impedance wasn't too critical.

> So one way to make the loop, assuming the gap is at the top, is to
> make one side out of coax (which becomes the feedline) and the other
> side out of solid rod the same OD as the feedline. Attach the center

<snip>
Yup! Once I had accepted the fact that the shield is the antenna, all the other loops I made with one half of the loop being solid wire, shorted coax pieces, cross-connects etc, all made sense. They all worked nearly the same except for some very slight inbalances in the directional pattern, and some small differences in the depth of the nulls. The light bulb turned on in my head, and now I could stop cutting up so much coax. <grin>

> Remember, too, that the current is there (in a receiving antenna)
> because we put a load across the gap by means of the coax feedline.
> Otherwise, any current would only be there to charge the capacitance
> of the gap (to a voltage corresponding to the EMF given by Faraday's
> law, less a tiny I*R drop in the conductor).

Aha! As in putting say a gapped director or reflector element built out of copper tubing in front or behind of my coax-built rx loop. Now that would be interesting, although most likely a mechanical nightmare.

Good info!

Yes, there would. But every watt delivered to that wire would be either
radiated or dissipated.

> You can make a transformer to match 50 Ohms to, say, 200 Ohms or
> so. Why not for 50 to 377? It's just another number.

That's right. You can make a transformer that converts the circuit V/I
ratio to 377 ohms. But this doesn't make a plane wave whose E to H field
ratio is 377 ohms. But you can have an antenna with a feedpoint
impedance of, say, 3 - j200 ohms, and a couple of wavelengths from the
antenna, the ratio of E to H field produced by that antenna will be 377
ohms. Another antenna, with feedpoint impedance of 950 + j700 ohms, will
also produce a fields whose E to H ratio is 377 ohms. In fact, you can
have any antenna impedance you'd like, and a few wavelengths away, the
ratio of E to H field will be 377 ohms, provided the antenna is immersed
in something resembling free space. But the fields in, on, or around a
377 ohm transmission line are unlikely to have an E to H ratio of 377 ohms.

You're trying to say that the 377 ohm E/H ratio of free space is the
same thing as a V/I ratio of 377 ohms. It isn't. Any more than 10 ft-lbs
of torque is the same as 10 ft-lbs of work or energy.

V and I will be in phase at the feedpoint of a purely resistive antenna.
This is true whether or not it's matched to the transmission line
feeding it, or whether the transmission line is matched to the antenna.
The relative phase of V and I at the antenna terminals has nothing to do
with whether the antenna or transmission line are matched. It also
doesn't matter what fraction of that resistance represents energy
dissipated locally and how much represents energy radiated.

> question.

You're right. The network analyzer can't tell you what's happening to those watts going into the antenna. Too bad. If it could, we'd have a really cool, easy way to measure antenna efficiency, wouldn't we?

But it's worse than that. If you connect the network analyzer to two series resistors, it can't even tell how much power is going to each one! And it can't even tell the difference between a 50 ohm resistor, a 100 ohm resistor on the other side of a 2:1 impedance transformer, a 100 ohm resistor on the other end of a quarter wavelength of 70.7 ohm transmission line, or a really long piece of lossy 50 ohm transmission line. Boy, they sure are stupid.

How come nobody complains that the impedance of a light bulb, an LED, or a loaded electric motor is resistive? It's too bad it is, too. Otherwise, the power company wouldn't charge us for the power we're using to run those things. Neither the power company nor the network analyzer knows or cares how much of the power going to a light bulb or LED is converted to light and how much to heat, or how much of the power going to an electric motor is doing work.

If we insist on separating all resistance into "dissipative" and "dissipationless" categories, we have to consider time. Within a small fraction of a second, most of the energy going into an antenna is dissipated -- mostly in the ground or (at HF) the ionosphere. So we'll have to consider that portion of the radiation resistance as "dissipative". The stuff that goes into space will take longer to turn into heat, but it will eventually. So the remainder of the radiation resistance is one that's initially dissipationless but becomes dissipative with time. Just think, we can have a whole new branch of circuit theory to calculate the time constants and mathematical functions involved in the transition between dissipationless and dissipative states! And of course it would have to be cross-disiplinary, involving cosmology, meteorology, and geology at the very least. There are textbooks to be written! PhD's to earn! Just think of the potential papers on the resistance of storage batteries alone! High self-discharge rate means a faster transition from dissipationless to dissipative. . .

Sorry, I digress. I just get so *excited* when I think of all the possibilities this opens up for all those folks living drab and boring lives and with so much time and so little productive to do. . .

But has this bastard creation really simplified things or enhanced understanding?

>>Now tell me, why can't you just make some 377 ohm transmission line

> Why would you need a 377 Ohm feedline for free space, when free
> space itself is the transmission line??

By golly, you're right. Design your transmitter for 377 ohm output and do away with the transmission line, too. Just let them joules slip right out, perfectly matched, right straight to free space. Voila!

> What's wrong with thinking of an antenna as a type of series
> Inductor, with a distributed shunt capacitance, that can be thought of
> as a type of distributed "L" matching network that transforms from 50
> Ohms to 377?

Because that's not what it does, and thinking of it that way leads you to impossible conclusions. The antenna is converting power to E and H fields. The ratio of E to H, or the terminal V to I are immaterial to the conversion process. You're continuing to be suckered into thinking that because the ratio of E to H in free space has the dimensions of

ohms that it's the same thing as the ratio of V to I in a circuit. It isn't. A strand of spaghetti one foot long isn't the same thing as a one foot stick of licorice, just because the unit of each is a foot.

> This is related to how you need to bend the ground radials of a
> 1/4 WL vertical whip at 45 deg angles down, to get the input impedance
> closer to 50 Ohms (as opposed to 36 Ohms or something like that if you
> leave them horizontal).

There are a number of ways in which an antenna and transmission line are similar. But don't take the analogy too far. Start with a quarter wavelength transmission line, start splitting the conductors apart until they're opposed like a dipole, and tell me how you've ended up with an input impedance of 73 ohms.

There are plenty of texts you can read, on all different levels, if you're really interested in learning about antennas, fields, and waves.

I am not 100% sure if this is the solution - but HAMCALC wants the
.bat file in the root directory, so in your case it's C:\

I have installed it in a directory and use the following .bat file to
call it:

```
echo off
cls
subst y: f:\hamcalc
y:
cd\
gwbasic \hamcalc\prog\intro
subst y: /d
f:
cd\hamcalc
```

as you see, I am 'subst'ituting the Y: drive with the existing
F:\HAMCALC In this directory ist the .bat file

Attention: under this f:\HAMCALC is another HAMCALC, so it's
F:\HAMCALC

\HAMCALC
\ (here are all the other dirs)

Is the GWBASIC.EXE either in the root directory or anywhere in one of
the directories with a pointer by the 'path' environment variable ?

Roy;
Hope you don't mind if I ask you a couple of questions about your
last sentence.
Given a 75 ohm dipole fed 100 watts with 75 0hm coax. Assume no
losses, now if the antenna's input impedance is changed to say 50 ohms
(non-reactive). You would have some loss with the mismatch between
the coax and antenna?
The transmitter would see 50 ohms?

Hi, I am thinking of getting a Yaesu 897 with the ATAS 120 antenna for both mobile and base operation. My problem is that I live in a condo which does not allow antennas on the roof. I have been thinking of getting the MFJ 1904 which is a 2' X 2" stainless steel base and mounting the ATAS 120 with an extension (to keep RF away from me and also to get it as close as possible to the cathedral ceiling). What do you guys think of such an arrangement.
Thanks

> the coax and antenna?

Mismatch does not cause loss (that is, conversion of electrical energy to heat), except that the loss of a lossy transmission line will increase (very slightly unless initial loss is great) when SWR is elevated. In this case, the line SWR would be 1.5:1, which would not cause a significant amount of extra loss even if the cable were very lossy when matched. So the answer is no.

> The transmitter would see 50 ohms?
>

The transmitter could see any of a variety of impedances, depending on the length of the 75 ohm transmission line. Only if the line were an exact multiple of an electrical half wavelength would the transmitter see 50 ohms, resistive. If the line were an odd number of quarter wavelengths, the transmitter would see 112.5 ohms, resistive. At all other lengths, the transmitter would see a complex (partly resistive and partly reactive) load.

There is a term called "mismatch loss", which is widely misunderstood in the amateur community because of its name. It doesn't really represent loss at all, but a signal reduction for other reasons. I've explained this before in this newsgroup, so if you're interested, you should be

able to find my earlier postings via http://www.groups.google.com.

The original question was *not* about co-phasing. It was about using another whip as a replacement for the missing half of a dipole. The second whip would be connected directly to the car body and become an extension of the body.

Totally different from co-phasing.

I'm building a simple radio telescope, using an array of dipole antennas, but I have a few questions. (Note: I've had a year of physics, but no electronics... so please go easy on me) ;)

1. I've heard the the dipole should be 1/4 of the wave-length above the ground... is this so that the total distance (antenna-ground-antenna) is 1/2 the wave-length (the fundamental mode)?

2. I've also heard that the cables connecting the antenna to the reciver should be in multiples of 1/2 the wave-length. How important is this?

3. To improve signal strength, I'm building three antennas. How far apart should they be spaced?

TIA!

R.

Roy Lewallen wrote:
>
> There is a term called "mismatch loss".

If a 50 ohm generator is connected to a 50 ohm resistor (or resistance), the maximum possible power is delivered to the load.

If the load is greater than or less than than 50 ohms resistor (or resistance) the power delivered to the load is less than the maximum possible.

The ratio of maximum power (50 ohm load) to actual power (<50 ohms or >50 ohms) is the mismatch loss. It is almost always expressed in dB.

The ARRL Handbook Chapter 17 discusses this topic.

Maybe it should be "maximum *available* steady-state power" which is
not always the same thing as "maximum "possible" power"? :-)

And the 50 ohm resistance can be the V/I ratio looking into a Z0-match
point with a high mismatch loss between the Z0-match and a mismatched
antenna, i.e. maximum available power (minus feedline losses) can still
be delivered to a mismatched load by doing the matching back down the
transmission line, e.g. an antenna tuner.

So where does the 33.33 watts actually go? The 100 watt number seems to
account for all of the transfer of energy.

Except for the amount of power input. Although you didn't mention it
explicitly, I assume SGCL2 inputs 33.33 watts. Obviously there's that
much more power being input to the network in this example that the
others we've worked on.

> Note

I note that interference takes place.

> feedline will do that if the voltages from the two sources are max+ at the
> same time.

Well, you won't get a phase reversal from reflection at the 150/50 ohm boundary as you would with the 150/450 ohm boundary in our other problem, so I think the 150 ohm feedline would need to be an odd number of 1/4WL's in order to put Vref1 out of phase with Vfwd1 at the first boundary. But since we're really interested in the relative phase between Vref2 and Vref1, and Vref1 becomes inverted at the 50/150 ohm boundary, you would want to maintain the phase of Vref2 by using an even multiple of 1/4 wave lengths of the 150 ohm line.

> b1 = s11*a1 + s12*a2 = 0V s11*a1 and s12*a2 engage in destructive interference.

>
> Pfwd2 = Pfwd1(1-|rho|^2) + Pref2(|rho|^2) + constructive interference
> 133.33W = 75W + 8.33W = 50W

I'll trade you a plus sign for your equal sign. ;-)

We also know that 133.33W = 100W + 33.33W.
So 100W = 100W + 33.33W - 33.33W. Which is equally revealing. ;-)

Maximum possible is correct. The maximum
"available" from the generator is a constant
value. The maximum "delivered" is the thing can be
lower than the maximum.

==========

Unfortunately, the use of the term "Reflection Loss" to descibe performance of amateur feedline + antenna systems at HF merely adds to the confusion.

"Maximum Available (or possible) Power" delivered to the load occurs only when there's a "Conjugate Match" between generator and load.

But a Conjugate Match does not exist. It cannot even be assumed. For the simple reason the internal impedance of the generator is never known. And it wouldn't make any difference to how the system is set up and operated if it was.

Even the generator (transmitter) designer doesn't know what the internal impedance is. He couldn't care less. It can vary all over the shop depending on what the load impedance is.

Hi Rapheal

If you are specifically aiming at radio astronomy be aware that the "pattern" of the antenna (in your case the "best strength" direction) will be affected by height above ground. The ground acts as a reflector of sorts. Have a wander through http://www.cebik.com and you'll see what radiation/response patterns look like. To give you an idea I once had a crossed dipole 3/8 of a wavelength above a metal sheet that radiated/responded mostly to signals about 20 degrees above the horizon and gradually less and less till directly above. This was of course for satellite use. You probably want a fairly vertical pattern to reduce local/man made noise so the spacing will be less.

In using an array of dipoles what kind of directional response are you after? This will govern their spacing, height above ground and so on. If you are feeding the dipoles to get a directional pattern, cable length does become something to consider but for a single dipole isnt very important.

What is your exact intended use, direction of operation and frequency. I'll try and be more specific...

Cheers Bob VK2YQA

All of this is common knowledge, or should be.

However, this gets beyond the basic idea of
mismatch loss. It was not my intention to get into
an expanded discussion of the various
contingencies, which have been discussed ad
nauseum in this forum. One should start with the
simplest case.

If an equipment is designed to work into a 50 ohm
load, and the load is not 50 ohms, a "return loss"
can be measured with a 50 ohm directional coupler.
No knowledge of the generator impedance is needed
for this. The return loss is also a measure of the
mismatch loss, if the generator resistance (50

ohms) is known. An impedance "transforming" network can improve the load impedance closer to 50+j0 ohms. The equipment will then perform as advertised.

In many kinds of circuits mismatch loss and conjugate match are important.

Folks,

Okay, I think my decision is in... The SGC-235 tuner. Does anyone have experience running power into this tuner, in excess of the "rated" 500 watts?

Cecil had a good idea, initial tune with low power, and then add full smoke later on. My operation will be SSB, peaks at 600-700 watts, give or take. And yes, I am willing to cap power output at around 600, if need be ;-)

Also, what configuration are you all using? Dipole, or long wire?

Thanks in advance again, and yes, Roy, here I go with the considerable expense... thanks!

I didn't say they were unimportant. I said they served only to add to the confusion when considering operation of the usual amateur installation when the generator internal resistance is unknown.

RFSim99 lets you easily see how (in)sensitive such a filter is to load
resistance and reactance. And if you're going to use it in a
transmitting (or receiving, for that matter) application, it might be
good to know that, since it may be rather difficult to control either
the load or the source impedance, especially over a wide frequency
range.

Cheers,
Tom

Agreed. But a Black Box to me implies you have limited
information from it. My point is that if someone gives you an
impedance plot of a resistive 50 Ohms, you will not be able to tell if
it is dissipative (lossy) or radiated resistance.

I was just reading that Joseph Carr calls radiated resistance as
a sort of "ficticious" resistance. I'm sure many here would argue
this description, but it kinda makes sense to me.

I'd be one of the people arguing. Radiation resistance fits every
definition of resistance. There's no rule that a resistance has to
dissipate power. The late Mr. Carr was quite apparently confusing
resistance with a resistor, a common mistake.

Why not call radiation resistance "real" resistance and loss resistance
"ficticious"? Makes just as much sense as the other way around -- that
is to say, none.

I was thinking of something like a sloping vee beam. One mast and the wires sloping towards the ground and supported a short distance off the ground. Maybe three wires with one common that is switched between one of two outer wires to change directions. It would be bidirectional and cover most of the earth. I have antenna books stored that have this sort of info, just can't get to them right now. I know it is in the ARRL antenna handbook, especially the older one.

Well, my point was that you don't need a transmission line for
free space because otherwise it wouldn't be wireless. But your above
point is well taken, that there is no current flowing in free space,
in an expanding EM wave, while there definitely is current in a

transmission line.

Certainly the EM wave will heat up ever so slightly any bits of
metal it comes across on the way to outer space.

So the remainder of the radiation
> resistance is one that's initially dissipationless but becomes

>

And the EM wave will theoretically continue forever, even if it is
in steradians (power dropping off by the cube of the distance?), so
perhaps eventually most of it will be dissipated as heat.

But, as you know, a capacitor also never fully charges...

But an antenna must be performing some sort of transformer action.
If you were designing an antenna to radiate underwater, or though
Jell-o, or any other medium of a different dielectric constant than
free space, you would have to change it's geometry. Even if it is E
to H, and not V to I.

If an antenna is not a transformer of some type, then why is it
affected by it's surroundings so much? They obviously are, just like
the primary's impedance is affected by what the secondary sees in a
transformer. Certainly having lots of metal in close proximity will
affect the impedance of your antenna.

>

Well, I'm not sure, but you would start off at an open, which
would be transformed to a virtual short. But from there, it sounds
like a complex mathematical derivation to get the 73 Ohms.

My point is that the 73 Ohms is dependant on the dipole's
surroundings, depending on how far from the ground and such, so it is
a transformer of some sort.

No. "Reflected" power isn't delivered to the wire. It's an analytical function that exists only on the feedline. If the feedline has no loss, the same amount of power entering the line exits the line. You can have any amount of "reflected power" you want by simply changing the characteristic impedance of the line -- with no effect on the power either exiting or leaving the line.

Yes, that's right. But if you want to dig deeper, you'll find that a
"displacement current" can be mathematically described which
conveniently accounts for some electromagnetic phenomena. It is, though,
a different critter from the conducted current on a transmission line.

An antenna can reasonably be viewed as a transducer. It converts the
electrical energy entering it into electromagnetic energy -- fields. As
is the case for any transducer, the stuff coming out is different than
the stuff going in. Think in terms of an audio speaker, which converts
electrical energy into sound waves, and you'll be on the right track.

Not transformer, transducer. More like a speaker than a megaphone.

> If an antenna is not a transformer of some type, then why is it
> affected by it's surroundings so much?

Egad, how can I answer that? If a fish isn't a transformer, then why is
it affected by its surroundings so much? If an air variable capacitor
isn't a transformer, then why is it affected by its surroundings so
much? What does sensitivity to surroundings have to do with being a
transformer?

They obviously are, just like
> the primary's impedance is affected by what the secondary sees in a
> transformer. Certainly having lots of metal in close proximity will
> affect the impedance of your antenna.

It is true that the equations describing coupling between two antenna elements are the same as the for the coupling between windings of a transformer. But a single antenna element isn't a transformer any more than a single inductor is a transformer. When you apply V and I to an antenna, it creates E and H fields. When you apply V and I to an inductor, it creates E and H fields. Both the antenna and inductor are acting as transducers, converting the form of the applied energy. If you put a secondary winding in the field of the primary inductor, the field induces a voltage in the secondary. If (and only if) the secondary is connected to a load, causing current to flow in it, that current produces a field which couples back to the primary, altering its current. Coupled antennas, or an antenna coupled to any other conductor, work the same way -- although localized currents can flow in the absence of an intentional load if the antenna is a reasonable fraction of a wavelength long.

But the single antenna isn't a transformer, any more than the single inductor is. Each is a transducer, and the secondary winding, or coupled conductor, is another transducer.

And it's really, really tough and requires some *really* creative (read: bogus) math to derive it from simply transmission line phenomena.

> My point is that the 73 Ohms is dependant on the dipole's

Not by itself it isn't. But if you can make a transformer by putting two antenna elements close together -- put V and I into one and extract it in a different ratio from the other. It's going to be a pretty lossy transformer, though, due to energy lost to radiation. (You'll find extra resistance at the "primary" feedpoint that'll nicely account for this.)

One of my favorites is King, Mimno, and Wing, _Transmission Lines, Antennas, and Waveguides_, and that's probably the one I'd choose if I had to select just one. It was reprinted as a paperback by Dover in 1965, and the paperback be found as a used book pretty readily and inexpensively. Kraus' _Antennas_ is my favorite text on antennas, and is certainly one of the most, if not the most, highly regarded. It's now in its third edition, and you can often find used copies of earlier editions at reasonable prices. For transmission lines, there's an excellent treatment in Johnson's _Transmission Lines and Networks_. I refer to Kraus' _Electromagnetics_ particularly when dealing with waves in space. And Holt's _Introduction to Magnetic Fields and Waves_ is pretty good for both.

There are a lot of others, each with its strong and weak points. But you can't go wrong with these.

Yeah, you know I just took a quick scan of the HF spectrum. Looks like most of the modern world has relinquished HF spectrum for more consistant, secure means of long range communications.
There's a few spanish speaking mariners off the coast of Chile on 8MHz, but they're waiting for some surplus AMPS cell service to show up. The same drunks on 75 every night bitching and moaning about not getting laid, 2 guys a day die at the mic on 40 trying to spark a nail while explaining their med
regiment, 20's got would-be broadcast engineers schmoozing us with swideband audio, effectively demonstrating how to make inefficient use of spectrum as the DX'ers yelling numbers across the pond. From there up to through 10 its kinda dead...except 27MHz. There's always an elevated noise floor and some potent SKIP signals on 27MHz.
Both amateur bands on either side can be dead quiet while half the iron EF Johnson ever made is pumping square waves on Channel 6. I really shouldn't mention 27MHz though because thats, well thats CB.
Its probably a result of that band selective propagation problem I noted earlier.
I really hate to be the devils advocate, and I have have enjoyed the romance with ham radio that many others from years gone by have experienced, but we may soon be exposed to the same hassle the 8-track got when cassettes showed up on the front seats of our Chevelles.
Unfortunately, the FCC has been reduced to auctioneers, directly accountable to scuzbucket politicians eager to sell off anything possible to maintain the facade.
The lucky ones leave the FCC to assume cushy positions at corporations they help during thier tenure, quite blatantly I might add. Hell, some have left to start
companies that intentionally try to destroy industries(LMR/SMR) to achieve thier means(certain cell carrier with push to talk feature)
I'm probably gonna send Newington money anyway. They irritate sometimes, but they're the biggest gun we have. I'd really miss the natural sound of an HF
radio set, and the character and tradition of our HF presense. How 'bout you?
My argument is that BPL should be high pass filtered with a 30MHz cut-off. When the leakage of data begins to propagate erratically in the lower
HF region, there may be fragmented co-node interference that may be a duplicate color code match, causing network disruptions.
Another more basic issue is, Commonwealth Edison can't keep thier 60Hz primary product from leaking. How the hell are they going to handle a sub

carrier service on ratty grids maintained by employees that think the power
is
good because your lights are on?
And finally, the sacrifice of the lower 28MHz (2-30) that is alleged to be
affected
will not drastically affect the massive volume of throughput that will be
crammed
down the throats of so many, or the massive volume of cashflow that will be
enjoyed by so few.

I told you, the 33.33W joins the 100W forward wave at the impedance
discontinuity and heads toward the load where a new 33.33W is rejected
by the mismatched load. Maybe that is the point of your confusion. The
33.33W that makes a round trip to the impedance discontinuity and back
to the load is not the same 33.33W that is reflected by the load. TV
ghosting proves that to be true.

>

"33.33W SGCL2" seems pretty explicit to me.

> Obviously there's that
> much more power being input to the network in this example that the
> others we've worked on.

We are also taking out more power than we previously were.

> I note that interference takes place.

Please note that the 25W reflected when SGCL1 only is on is 35.36V at
zero deg, and 0.707A at 180 deg. When SGCL2 only is on, the 25W not
re-reflected is 35.36V at 180 deg, and 0.707A at zero deg. That's why
they cancel when both are on.

Nope, you are wrong about that but I'll let you figure our your own error.
The only voltage phase reversal in the given example is in the re-reflected
wave associated with the 8.33W. Vfwd1 travels 1WL while Vref2 travels 1/2WL.
That is enough to put them 180 degrees out of phase. Vfwd1(|rho|^2) undergoes
zero phase shift. Vref2(1-|rho|^2) undergoes zero phase shift.

Point is that "maximum possible power" will cause a lot of transmitters
to exceed their maximum power rating and overheat.

Hi Bob,

Thanks for the quick reply. That Cebik site is a great resource, I'm still going through the antenna basics article, but "wi're we using wire" has already shed some light on things.

Here's a bit more detail on my project: I want to set up an antenna in such a way that most of my signal will be natural (ie not man made radio). Then, over a year, make a map of the sky as seen from my back yard. Basically my plan is antenna into amplifier into A/D converter into the serial port of a PC in my basement. The PC will poll the antenna every couple of minutes, and use the signal strength to make a stripchart, and an overall skymap where each pixel represents the signal strength at a given day and time.

I think I might start with one antenna, to keep things simple starting out, and then add on more antennas if it seems practical.

Thanks again,

R.

What might be of interest in this discussion is that after he derives the impedance of free space, he uses that to find the Radiation Resistance of a short dipole for d<<W. Where d is the length of the dipole and W is wavelength. (I did not want to do Greek letters). He ends up with an equation of the form

R=377k(d/W)**2 or R=790 (d/W)**2.

As a sanity check let d/W=1/2, which violates the <<, but still gives a fairly close answer of 197 Ohms, compared to the actual 168 Ohms. Note that this is not the same as Feedpoint Resistance because it is not referred to the current maximum. Kraus does not actually say this, but seems that the near field would be the mechanism for "matching" this to the far field 377 Ohms. The transmitter only sees the feedpoint, the rest of the universe sees the whole antenna.

If I interpret it correctly, this 197 (168) Ohms in independent of where you feed the dipole. Kind of hard to boil several pages into one paragraph, especially since most of this stuff I haven't seen in decades.

There's always a helluva wrangle over most every aspect of
HF at each and every WARC, gotta be some serious interest there somewhere.

>
> My argument is that BPL should be high pass filtered with a 30MHz
> cut-off.

There are a number of public safety agencies who still make serious use of lowband
VHF below 50 mHz, all the trunked systems nothwithstanding. Converting those to
UHF or up is a big $$$$$ proposition which just aint gonna happen iin the financial
climate facing those users for the forseeable future
. The state I worked a career for that uses a series of frequencies in the 42mhz
region for statewide public safety comms
would love to abandon it all in favor of a trunked UHF or above system but can't find
the ~$250mil it'd take to do the job. I'd expect that state and several others that
I know are on low VHF to have some pretty strong language for the FCC on the BPL
issue.

If FCC wants a real hornets nest to descend on DC they can assure it by approving
the
BPL docket without many very serious limits, big chunks of frequency exemptions and
much other machinations to releive in advance a huge amount of what will be real

trouble for them if they don't. And no one knows if it would even work acceptably then, much less if there will ever be a viable business plan stem from it all. Who knows what emerging technology will render the whole scheme obsolete sometime next week?

Dick

Hi Paul,

This is first for me, find attached the EZ file for one of several models I worked on. Let me know how useful it is (it may be the wrong one, but it is certainly very close to what I published).

Dr. Slick wrote:
"I don`t have that book."

I don`t have Kraus either and I miss it.

Space has a magnetic permeability and a dielectric constant. The square root of their ratio is the characteristic resistance of space. It is 376.7 ohms = 120 pi ohms.

The reciprocal of the square root of the product of the permeability and dielectric consrtant of space is the velocity of EM radiation propagation. It is 300 million m/sec.

The above is courtesy of King, Mimno, and Wing, in "Transmission Lines, Antennas, and Wave Guides", on page 73.

The authors must have considered the information important as they repeated it on page 117. They followed the repetition with a discussion of the radiation resistance and input resistance of an antenna. They note that radiation resistance can`t be measured between two terminals in a circuit. The I squared R of the antenna power does not conveniently compute as might be expected with circuit terminals, as current is a variable along an antenna in most cases.

Best regards, Richard Harrison, KB5WZI

Dr. Slick wrote:
>
> But an antenna must be performing some sort of transformer action.

Not quite - but there is a word for what it does: it's a transducer.

A transducer is any gadget that converts energy from one form into a *different* form. Examples include a loudspeaker (electrical energy to sound/mechanical energy), a microphone (the reverse), a light bulb and a photocell.

From that point of view, a resistor is a transducer that converts electrical energy into heat energy... but it also has some useful electrical properties :-)

An antenna is a transducer that converts electrical energy into E and H fields, and the reverse.

You'll also notice that all practical transducers convert some of their input energy into heat energy.

It's a useful word for a useful idea.

(Cecil - can your IEEE Dictionary help us with a formal definition?)

On the other hand, if you insist on using the word "transformer", you'll keep on believing you can work out new facts about antennas from what you already know about transformers:
> If an antenna is not a transformer of some type, then why is it
>affected by it's surroundings so much? They obviously are, just like
>the primary's impedance is affected by what the secondary sees in a
>transformer.

That's a perfect example of the trap, because in reality it's not "just like". An antenna also has E-field interactions with its environment that a transformer doesn't have, so any resemblance will literally be only half-true.

Hi Raphael

Okay understand a bit more now..

The question I have to then ask is in mapping the sky are you hoping to see higher and lower areas of RF density? To do this you will need some kind of steerable system and poll for signal strengths at a series of given co-ordinates. This would be very ambitious as making a narrow steerable beams is a science in itself. (You can do it mechanically or electrically. ie a dish/steerable yagi or by changing the phasing relationship between the antenna elements. With a computer the second method can achieve very narrow beamwidths by using the signal null instead of a peak. Very fiddly though. Never seen the software to do it...)

If you are only intending to capture information with it pointed in one direction and using the earths rotation to build a east-west traverse then this would be a lot simpler. What you havent mentioned is the frequency of operation as this governs the antennas size and design. You said an A/D.. Is this after a receiver or are you direct sampling and building up FFT buckets to get a VLF spectrum display? At such low frequencies antenna directivity is an entirely different exercise. If you are talking about (say) 3-30MHz a shielded magnetic loop will give you some directivity and reduction of man made noise. Not sure about VLF antennas. A guy I use to work with has done some work in this area (http://www.zeta.org.au/~ollaneg). It has some excellent info on data in noise techniques as well.

I realise I have digressed a little. Maybe I should read what you have said <grin>

Cheers Bob

Hi Bob,

Thanks for the quick reply. That Cebik site is a great resource, I'm still going through the antenna basics article, but "wi're we using wire" has already shed some light on things.

Here's a bit more detail on my project: I want to set up an antenna in such a way that most of my signal will be natural (ie not man made radio). Then, over a year, make a map of the sky as seen from my back yard. Basically my plan is antenna into amplifier into A/D converter into the serial port of a PC in my basement. The PC will poll the antenna every couple of minutes, and use the signal strength to make a stripchart, and an overall skymap where each pixel represents the signal strength at a given day and time.

I think I might start with one antenna, to keep things simple starting out, and then add on more antennas if it seems practical.

Thanks again,

R.

Dr. Slick wrote:
"What does it say?"

I don`t have Kraus, unfortunately.

I do have Arnold B. Bailey`s "TV and Other Receiving Antennas". Bailey covers more antenna territory than most, and does an excellent job of it. Bailey also includes a catalog of antenna types, all sized for 200 MHz for easy comparison.

Bailey says the surge impedance of an antenna is inversely proportional to the capacitance per unit length. Reminds one of a transmission line. This is non-uniform, so Bailey has an empirical equation which says the larger the periphery of the rod, ther smaller the average surge impedance.

The ratio of the electric field to the magnetic field surrounding an antenna must be related to the ratio of volts to amps in the antenna wire (the surge impedance).

The surge impedance of a thin-wire 1/2-wave dipole from page 500 is 610 ohms (average).

The surge impedance of a fat-cylinder 1/2-wave dipole from page 502 is 240 ohms (average).

Pattern and gain are identical for both antennas. But, Dr. Slick may be on to something after all. The bandwidth of the fat antenna is about 3X that that of the thin. In antennas, bandwidth is often an indicator of match.

Best regards, Richard Harrison, KB5WZI

RFSim99 seems to be a good program, but after 2 years of ADS and
how poorly it predicts how the "bench" should react (esp. at 1-2 GHz),
I'll stick to actual prototypes for now.

Ian, G3SEK wrote:
"Examples include a loudspeaker---."

Good transducer example. Its problem is abysmal efficiency, even if better than the usual incandescent lamp.

The loudspeaker`s efficiency can be improved by a better match to its medium. The usual loudspeaker is small in terms of wavelength. A result is that it is capable of exerting much force on a small area of a very compliant medium, air. Air could better accept power exerted over a much larger area, especially at low frequencies, with less force required to make the air move..

We have a high-Z source and a low-Z sink in the loudspeaker and air. Conversion from electric power to mechanical power can be more efficient through better impedance matching. Two solutions are often used for a better match, a larger loudspeaker or a horn between the loudspeaker and its air load. The larger speaker is directly a better match. The horn is an acoustic transformer. They both improve energy conversion efficiency.

Best regards, Richard Harrison, KB5WZI

Understood. But you have to admit that transformers and
transducers have some similarities. You will still have to optimize
the windings and magnets and size/shape of the speaker cone for
optimum power tranfer of a single tone. And you will have to have to
change the design if you decide to transmit sound underwater.

I see your point, that the primary could be considered one
antenna, and the core material like free space, and the secondary
would be the receive antenna. But i suspect even a single
transducer/antenna can be optimized for maximum lines of flux through
a core at a particular frequency, or max ERP in the case of the
antenna. Otherwise we wouldn't have to tune these things.

Your point has been well taken, Roy. But you have to admit that radiation resistance is not a easily understood concept (which is why it may be a common mistake), so for someone to call it a "fictitious" resistance can make sense, in the sense that it is not a dissipated resistance. After all, "Imaginary" numbers are well accepted. And from an arguing sematics point of view (which is unfortunately necessary sometimes), even you call it "radiation resistance", which means that it is obviously not the same thing as a dissipative resistance like a 50 Ohm resistor.

That being said, rest assured, Roy, that you have convinced me!

Roy:

Great analogy!

The characteristic acoustic impedance of air (standard temp &
pressure) is about 413 Rayleighs (or Pascal-Seconds/cubic meter).

Do we worry about matching 8 ohms of electrical speaker impedance to
413 Rayleighs? C.f. Paul Klipsch and the Horn speaker.

I wonder if much of the antenna radiation resitance/Tline
impedance/reflection/intrisnic impedance of free space confusion stems
from use of the same words to describe things that may be modeled
mathmetically identically, but have different physical modalities?

In heat sink calculations, for example, we use "thermal resistance"
and an Ohm's law model but few would confuse ohms of resistance with
degrees C/watt.

Where does the loss occur? If you have 3 db of mismatch loss, is it
in the coax, tank circuit?

The loss in "mismatch loss" refers only to the fact that the power delivered by the generator to the load is less than it would be if the load resistance were the same value as the generator resistance, in other words if the load and generator were "matched".

The best way to get a handle on this subject is to draw a diagram of a generator with voltage V=10, an internal resistance of 50 ohms, and a load resistor of R ohms. Let R vary from 1 ohm to 100 ohms and calculate the power dissipated in the generator resistance (50 ohms), the power in the load resistance (R), and the total power. Plot a graph of the three quantities. The load power goes through a maximum when R=50 ohms.

The maximum power dissipated in the generator resistance is 10^2/50=2 W, which occurs when R=0 ohms. The minimum power dissipated in the generator resistance is 3.33^2/50=0.22 W which occurs when R=100 ohms. When R=50 ohms, the load power is 5^2/50=0.5 W (the maximum value), the dissipation in the generator resistance is 5^2/50=0.5 W and the total power is 10^2/100=1 W.

_Fields_and_Waves_in_Communication_Electronics_, Ramo, Whinnery,
& Van Duzer. Pages 647, 648, sections 12.05, 12.06.

The feedpoint current of a dipole is caused by the in-phase superposition
of the forward current and reflected current at the balanced feedpoint
of a standing wave antenna. A 1/2WL dipole and an open 1/4WL stub have
similarities. The deviation of the feedpoint impedance from zero ohms
gives an indication of the losses due to dissipation and radiation.

In which case, it is a phased vertical array, not a dipole. With
a spacing of 1/8WL, one can get 4 dB gain that way.

What does Terman say in Sec. 4-11?

"The distance l1 from the load, and length "a" of the stub, are chosen that the reflected wave produced by the shunting impedance of the shunt line is equal in magnitude and opposite in phase to the reflected wave existing on the line at this point as a result of the reflection from the load impedance ZL, there is no reflected wave on the generator side of the stub line as a result of cancellation of the two reflected waves."

Terman said about the same thing about cancellation of the reflected wave in a waveguide. Terman offered several methods to generate the offsetting wave in a waveguide, and there are several ways to generate a wave which produces cancellation on a transmission line, too.

Kraus comes up with Z=73 + j42.5. He then goes on to say that an actual dipole is made a few % shorter, which yields 65 + j0. When I did an EZNEC calculation on a 1/2 wave dipole at 3MHz, I did not quite get that. For a #30 wire in free space I got 76.81 + j43.89 at 3 MHz, and 72.88 + j0.3465 at 2.94 MHz.

I let EZNEC tell me what the wavelength was, and used 1/2 of that for the length of the dipole.

Hi Jack,

Someone must, or we would see more 600 Ohm speakers.

It is facile by half to simply accept the end product of design and anoint it as an example of a general solution. There are many antennas that are NOT 50 Ohms. What they ARE is actually of no consequence except in the sense of efficiency and mission (the antenna cares not a whit about either).

I have many examples of 2 Ohm antennas (and lower) and of 600 Ohm antennas (and easily higher) and ALL can be induced to radiate all of the power applied to them. The distinguishing factor across the board is that each hi-Z antenna presents similar, physical characteristics to all other hi-Z antennas; and each low-Z antenna presents similar, physical characteristics to all other low-Z antennas. All couple power to the same load of the ï¿½ther. Clearly impedance and size are correlated and it is up to the designer to accommodate losses to achieve similar performance. The same statement is equally applicable to speakers of any impedance.

Is the antenna transforming its Z to that of the ï¿½ther? Of course it is just as the speaker is. Are they both transducers? Of course they are when transducer is applied loosely (but strictly speaking - no). Injecting this notion that transducers are a class distinct from transformers is simply myopic to force an argument. No sooner is the notion introduced than we find the correlative transducer of the receive antenna introduced to recover the power - now transformed (and very inefficiently one might add). The remainder of that power becomes part of the background noise of the cosmos (far more of it than is ever recovered for actual use).

Transducers, as a class, are far more prone to the loss through resistance than transformers - by definition. The speaker is feeding a lossy medium of air, and the sonar is feeding the less lossy medium of water. The difference is in the compression characteristics that turns power into heat. Core loss of the transformer is not due to compression, but is a direct analog (and electrons bumping into each other and atoms does constitute a form of compressive loss). There is no loss in space/ï¿½ther but neither are there any phonons, the classic

transport of transducer emission and coupling. If an antenna is to qualify as transducer, it must be with the proviso that it is distinctly different from every other transducer in lacking the common transport mechanism of phonons. This is like say walking is a form of mass transportation if you simply ignore the word mass. To support these specious forms requires enormous exaggerations.

Another transducer available as a common example (or perhaps not for less well-heeled equipment) is found in the Collins mechanical filter for interstage coupling. It has both input and output transducers that couple the mechanical (and thus heat-prone) energy into nickel-steel resonant disks. Nickel-steel is obviously less compressive than either air or water, and exhibits far higher Q (which is a factor of both antennas and transducers - in their medium) to the advantage of the circuit. To any bench tech working on receivers, they would unhesitatingly call these IF Transformers.

Does an antenna "transform" any Z to another Z? The process is obviously performed with concomitant and equivalent issues of efficiency regardless of the term inserted between quotes. Does the term substitution bring any change, or does it correct any error? No. It is a tautology to suggest that "transducer" is appropriate when every presumption finds a corresponding "transducer" necessitated by the force of discussing fields (how does one know these fields exist without the absolute necessity of completing the transformer action?). One may "know" in the purely abstract sense, but such knowledge through the centuries has rarely preceded the actuality of observation in the real transformed world.

The distinction between transduction and transformation does not preclude the sense of an antenna serving as a bridge between two system impedances. Neither hi-Z nor low-Z structures have a stranglehold on design, except through economy. We commonly employ very low-Z sources (transistors) to feed modest-Z loads (a common quarterwave antenna). The economic factor of that load (a quarterwave at 160M) is sometimes unsupportable and yet we find very few short, low-Z antennas designed with direct feed from the same low-Z transistor. Economy again forces some form of transformation (I would hesitate to call a Tuner a transducer) in that the commercial market sees very little sense in building low-Z sources for an incredibly small niche who would refuse to pay the price. Instead, commercial design accommodates to one Z and expects the user to transform it along the way. The same logic extends to, and through the antenna.

Hi Nic,

It would seem that there is the necessity of a lag introduced
somewhere for this to make sense. In other words, some delay between
successive emissions of energy.

RF already being time sensitive in the sense of the common 360ï¿½
alternation of polarity would suggest that the previous field must not
follow the successive field in time order (otherwise there is nothing
to push as the former has already collapsed in synchrony to that which
follows). This thus presumes that the "first" field found nothing to
impede it; and it pushed free, but began to collapse some distance
out. As it did so, its transit space added lag and the original found
itself in competition with the next field emerging and they both
jostle out like passengers entering an airport moving walkway (or
escalator).

Mind you, this is simply my guess at the intent of the author's words. I would suspect they are more the product of his having seen or his having presented you with an illustration of fields that demands this discussion. You may find this more illuminating if you were to search for illustrations of field activity close to the antenna (or the discussion of magnetic lines emanating from the sun).

Bill;
Thanks, that all makes sense. Can you consider a Transmitter to
have an internal resistance like the generator that changes with the
plate and tune controls?
If I have a 100 watt transmitter and my wattmeter shows 3 watts
reflected. Is 3 watts actually being dissipated in the tank and final
PA?

Sorry to ask such simple questions. I did search through Google on posts on this subject, just never could find the answer I was looking for.

Hi Dilon,

Does it become 3 watts hotter under the same drive conditions without the reflected power? You would be surprised how few pundits actually discuss this in these terms. Of course everyone would be surprised if anyone attempted to perform this chore.

I like to include this jab at those who rave on about the impossibility of knowing the internal resistance of a transmitter and are satisfied to squeak out 100W RF for 250W DC in.

Indeed, and not only that, the generator (ham transmitter) is commonly
neither a linear system nor time invariant. Also, maximum power
(conjugate-matched load) from a linear generator is generally not the
most efficient case. A great many generators and amplifiers are
distincly NOT designed to deliver power to a matched load, but rather
to deliver power efficiently to a specific load which is mismatched
with respect to the output impedance of the generator/amplifier.

There are times when knowing that a generator is a linear 50 ohm
source (within some small tolerance) is important--I deal with them
all the time in the work I do--but in a typical ham transmitter
application, that's very seldom if ever the case.

Cheers,
Tom

Nic Santean wrote:
"-from "The Beginners`s Handbook of Amateur Radio" by Clay Laster, page 260."

Clay used many words to say the signal propagates too far to get back to the radiator. It continues its journey away from the radiator.

Radiation is really caused by exchange of energy between alternating magnetic and electric fields. They produce each other when they alternate. Static fields don`t radiate. They soon fade away.

J.C. Maxwell speculated that displacement current produces the same alternating magnetic lines as conduction current does. He was proved right.

"Static" magnetic and electric fields move out into space when current flows and charge builds. When they are no longer changing, the fields at some distance have reached practical limits and stop expanding. Alternate these fields, and the fields can build each other and travel on and on.

A dumb question, if you want run 700 watts why not buy a tuner designed to handle 900~1000 watts. That watt rating is the maximum it was designed to handle. I know that you have heard that X run his xxx watt tuner, xxx watts over it's rating and has been doing for whatever, But sooner or later, more likely sooner, you will hear about the catastrophic failure his system had, and he can't figure out what caused it. But, always remember "You paid for it, you have right to destroy it"

Roy has clarified this adequately already.

Ok, I was half correct then. Two transducers make up one
transformer.

Certainly two dipoles very close to one another will affect each
other's impedance.

And a regular transformer with a core can definitely be affected
by a close EM-field.

Antennas, John Kraus, McGraw Hill 1950, Chapter 5-6, pages 143 to 146
gives a complete derivation for a 1/2 wavelength Antenna.

You need some Calculus and infinite series to understand the derivation.

Jack, K9CUN wrote:
"I have referred to my various engineering texts on antennas and transmission lines and can not find any discussion of antenna "vigor"."

I did not copy my statement. Vigor is defined in my "American College Dictionary as: "1. active strength or force---".

A rod in free space becomes excited and accepts energy, which it must re-radiate, when it is swept by a passing wave of its resonant frequency. Its first resonance is near a 1/2-wavelength. At frequencies slightly off-resonance, little current flows in the rod due to the opposition of its reactance.

You may have seen a mechanical analogy in the vibrating reed frequency meter.

Best regards, Richard Harrison, KB5WZI

But a speaker is designed for broadbanded operation, 20-22kHz, not
just one frequency like many antennas.

I'm sure a speaker optimized for one frequency alone will be much
different than a broadband one.

Yep, and an automobile can be optimized for maximum acceleration. Good
argument for considering an antenna a type of automobile, no?

Y'see, if you really, really want an antenna to be a kind of automobile,
you can cook up a bunch of reasons to convince yourself that it is. The
same method works for astrology and fortune telling, too.

Yes, the following people, plus others:

E. Hallen
S. A. Schelkunoff
Ronold King
F. G. Blake Jr.
David Middleton
Charles W. Harrsion Jr.
C. J. Bouwkamp
M. C. Gray

These people have published papers on the topic in the Proceedings of the I.R.E., Journal of Applied Physics, Quarterly of Applied Mathematics, and in the case of Hallen's classical paper, Nova Acta (Denmark). Schelkunoff and King and Harrison, at least, have written books. Simplified derivations that are valid for a limited range of antenna lengths and make certain assumptions about the current distribution can be found in any antenna text. I believe Reg uses an method similar to one of those in some of his programs.

John Kraus (W8JK) is an American, born in Michigan, who received his Ph.D. in physics from the University of Michigan in 1933. After WWII he went to Ohio State University, where he's been a professor since. For some time, he was also director of the radio observatory there. He's written a number of books, including _Big Ear_, about radio astronomy. He was made a Fellow of the IEEE in 1954 and elected to the National Academy of Engineering in 1972. Among his awards are the U.S. Navy Meritorious Civilian Service Award (1946), Sullivant Medal (OSU's top award, 1970), Outstanding Achievement Award of the University of Michigan (1981), IEEE Edison Medal (1985), and Distinguished Achievement Award of the IEEE Antennas and Propagation Society (1985).

He's now in his 90's and, by a recent account, still active and sharp.

Rich and Bob thanks for the suggestions. I don't have a balcony that is wht I have been struggling with a good set up. The ground plate is rather large 2 feet X 2 feet and it is a 1/4 inch thick and according to MFJ provides the equivalent ground of a car. I think using an extension probably is a bad idea since the ATAS requires to be in direct contact with the ground. I am now thinking of mounting the ATAS directly to the ground plate and if I need to add some radials. What do you guys think.

> reflected. Is 3 watts actually being dissipated in the tank and final
> PA?
>

No.

If the transmitter output is 100 W and the
reflected power is 3 W, then the 100 W is the
difference between 100+3=103 W (forward power) and
3 W (reflected power).

The question "where does the reflected power go?"
never seems to have an acceptable answer. Very
strange.

A good way to look at is as follows: The junction
of the transmitter output jack and the coax to the
antenna is a "node", which is just a "point" or
"location" where the jack and the coax meet. At
this node the voltage is exactly equal to the
voltage output of the amplifier (VPA) and also the
voltage across the input of the coax (VCOAX). The
voltage VCOAX) across the coax is equal to the
phasor sum of a forward voltage wave that travels
toward the antenna and a reverse voltage wave that
is traveling from the antenna backward toward the
transmitter.

Also, at the node, IPA is the current from the PA
and ICOAX is the phasor sum of a current wave that
travels to the antenna and a return current wave
that travels toward the transmitter.

At the node, the IPA current and the ICOAX current
are exactly equal and in the same direction
(toward the antenna). At the node the IPA current
is equal to the ICOAX coax forward current minus
the ICOAX reflected current. In other words there
is an *EQUILIBRIUM* at the node between VPA

voltage and VCOAX voltage, and an *EQUILIBRIUM* between IPA current and ICOAX (forward and reflected) current.

This explanation accounts for everything that is going on at the node. The answer to the question "where does the reflected power go?" is the following: "It is a nonsense question that has caused nothing but misery". The reflected power does not actually *GO* anywhere. The correct answer is that forward and reflected coax waves always combine precisely and exactly with the voltage and current that is delivered by the PA. The voltage and current at the junction are correctly accounted for. The basic principles here are Kirchhoff's voltage law and Kirchhoff's current law, as applied to the node. You can study Kirchhoff's laws in the textbooks.

If we apply these laws and calculate the 100 W power out of the PA and the 100 W power that is dumped into the coax, they are exactly equal. They cannot possibly be unequal. The power delivered is the real part of the product of VPA and IPA (100 W), which is identical to the real part of the product of VCOAX and ICOAX (100 W).

Observe carefully the following: We do not need to know anything about the PA and its circuitry. The PA is nothing more than an anonymous "black box". In other words, any 100 W (output) PA will perform exactly as I have described.

I agree that it makes some sort of sense to call radiation resistance a "ficticious resistor". It makes no sense to call it a "ficticious resistance" -- any more than you'd call the capacitance of a short antenna a "ficticious capacitance". It only advertises a lack of knowlege of the principles of basic electricity.

I was going to point this out as a relationship: Zo=SQRT(L/C) for a
transmission line. You adjust the ground radials of a 1/4 WL vertical
to go from 37 Ohms to 50 Ohms, by bending them 45 degrees, which is
reducing the shunt capacitance (radial to ground), thereby increasing
the impedance, similar to the transmission line equation (impedance
inversely proportional to distributed capacitance).

Thanks for pointing this out, Richard.

I'm not sure what you are getting at here. I understand that the
thicker radials give you broadbandedness. What's the definition of
"surge impedance" versus regular old "impedance"?

TV ghosting is primarily the result of multipathing, which is external
to the antenna system.

> The only voltage phase reversal in the given example is in the re-reflected
> wave associated with the 8.33W.

How are you determining your phase reversals? Don't forget that phase
reversal on reflection occurs when a wave encounters a more dense medium
(or a higher impedance).

Most simple derivations for the input impedance of a dipole assume it's infinitely thin. The general problem of a dipole made from wire of finite diameter is a lot tougher, and is the topic of the papers by the authors I listed in another recent posting. With EZNEC, you'll find that the dipole impedance will continue to change as you make the wire diameter smaller and smaller, until it gets too small for the program to handle at all.

Roy Lewallen, W7EL

Steve,

25 mm is rather skinny to go 8.3 meters with. However, the following should work. I assume the tubing is available in 3 meter lengths. 10 foot lengths would be even better.

Get four 3 meter pieces, and cut one down to 2.3 meters. Now bolt and center this 2.3 meter piece to the side of one 3 meter pieces. The 2.3 meter piece will be the top of your antenna, the 3 meter piece the bottom. Now bolt the remaining 3 meter pieces to the bottom piece, and you should have an 8.3 meter boom. Whatever you do, do not use brass or copper hardware. You might want add a strap to the top side where each of the 3 meter pieces butts up to the 2.3 meter piece.

1400. Wanted: SWAN Mobile Antenna Info

Newsgroup: rec.radio.amateur.antenna
Date: 2003-07-17 19:44:09 UTC
From: Norm VE3CZI <ve3czi@arrl.net>
Message-ID: <u8DRa.1913$tJ4.167399@read1.cgocable.net>
Source record: 112449
Cross-posted to: rec.radio.amateur.antenna,rec.radio.amateur.boatanchors

I recently "saw" a very interesting Mobile Antenna Designed and Made by SWAN Electronics in the '60s era.

It covers 80 - 40 - 20 Meters. Has One coil with two variable Capacitor arrangements tapped on the coil for adjustment for 40 & 20 Meters. There is access through a plastic cover to tune the capacitors.
It has a 4 ft rod below the coil, with this switching assy in center and a CB Whip on top.
It is totally automatic ie: electronic switching..no manual or relays...very interesting design.

** Can anyone recollect what the model Number is of this Antenna might be? There are NO markings on the Antenna.
** Has anyone got any information on this Antenna?

Tnx & 73...Norm VE3CZI

==========
Tom, To add a bit more -

50-ohm generators as used in laboratories (so that measured reflexion loss, mismatch loss etc, mean something) are effectively constant voltage generators in series with a 50-ohms resistor, or constant current generators in shunt with a 50-ohm resistor. They may be followed by an ampifier whose output impedance is held constant at 50-ohms by some automatic means. None of these circuits bear much resemblance to a pair of 807's and a tuned tank.

The best that can be said about Rg of the usual HF radio transmitter is that Rg is indeterminate. IT EVEN VARIES AS THE LOAD IMPEDANCE IS CHANGED which most of the Guru's contributing to this newsgroup appear to be unaware of or at least choose to disregard. So what does "adjusting RL to equal Rg" mean? To use it in a description of feeder + antenna behaviour further propagates myths, including those surrounding SWR, forward power, reflected power, SWR meters, etc.

Does Terman ever bother to mention Rg of a Tx PA? If he doesn't it can't matter very much to him. The ARRL handbook, when numerically designing a transistor linear HF PA, makes no mention of Rg.

Trouble is, Terman didn't say anything about what happens to the
intrinsic energy that existed in the waves before they were
canceled. I say the energy in rearward-traveling canceled reflected
waves is reflected back toward the load. Jim (and others) disagree
even though we know that all the energy winds up incident upon the
load.

Dr. Slick wrote:
"What`s the definition of "surge impedance" versus regular old
"impedance"?"

Arnold B. Bailey treats this better than anybody I`ve seen. But, there are many treatments. The regular old impedance of an antenna depends upon its termination.

Surge impedance of an antenna depends on its conductor`s inductance per unit length and capacitance per unit length. In the antenna these are not uniform as they are in a transmission line, and average values have been found useful.

Best regards, Richard Harrison, KB5WZI

Hi All,

The derivation of dipole electrical characteristics comes by neither
thin nor thick (cylindrical) elements but through a simpler
(conceptually, not mathematically) work described by S.A. Schelkunoff
in "Advanced Antenna Theory," John Wiley and Sons, 1952.

Schelkunoff approaches the design as merely the extension of the
transmission line and he answers the issue of the antenna (the thin
wire form) being non-linear (the presumed incremental
inductance/capacitance is not constant along the length of the split
transmission line) by simply employing conical structures.

The Biconical Dipole "develops a transverse spherical (TEM) wave
analogous to that on a conventional transmission line" (reference
"Antennas and Radiowave Propagation," Robert E. Collin, McGraw Hill,
1985). "Thus the biconical antenna theory provides a theoretical
basis for assuming a sinusoidal current distribution on thin-wire
antennas."

Like any transmission line terminated in its own character impedance,
the Biconical Dipole (within limits imposed by size and apex angle)
also presents a wide frequency range exhibiting a constant radiation
resistance (about 160 Ohms across three octaves, by my margin notes).

The easiest validation of this is found in the Discone.

Schelkunoff's method is elegant, and one that lends itself to relatively simple calculation -- in closed form -- with a computer. However, it doesn't give results which are in as good agreement with measurements than some other methods, so some assumptions made in his derivation aren't completely correct. A good summary of various methods and their validity appears in David Middleton and Ronold King, "The Thin Cylindrical Antenna: A Comparison of Theories", _Journal of Applied Physics_, Vol. 17, April, 1946.

The program for calculation of the "Field Day Special" antenna (ftp://eznec.com/pub/fdsp~.exe) uses Schelkunoff's method, and it's perfectly adequate for the purpose.

Of course, these days we can easily do very accurate calculations from very fundamental equations with a computer using the method of moments or other methods. There's a very good description of the method of moments in the second edition of Kraus' _Antennas_. I assume it's also in the third edition, which I don't yet have.

> to the antenna system.

:-) I'm talking about TV ghosting due to reflections on the transmission line between a TV test generator and a TV receiver. The only "multipathing" involved is the different paths taken by the reflected waves inside the transmission line.

>>The only voltage phase reversal in the given example is in the re-reflected

>
> How are you determining your phase reversals? Don't forget that phase
> reversal on reflection occurs when a wave encounters a more dense medium
> (or a higher impedance).

Nope, a voltage phase reversal occurs when a wave encounters a *lower* impedance. A voltage wave encountering a higher impedance does not reverse phase. In the earlier example, the only lower impedance encountered is by the rearward-traveling wave flowing back into the impedance discontinuity. I repeat, Vref2(-rho) is the only voltage phase reversal.

Actually, I read about this in Don Johnson of Screwdriver antenna fame's book on mobile radio operation. IIRC, the folks experimenting with it put the second whip on the far end of the car - tied to the frame, ie grounded - not driven. When tuned to resonance an increase in RF current in the car body was noticed and I think they also saw about a 3db increase in radiated signal. I imagine it's not very popular because of the difficulty of tuning two antennas instead of one, and the visual aspect of a second large antenna on the vehicle. It just isn't that practical even for a 3 db increase in signal.

It wasn't presented as being a dipole or any form of phased array. Just as empirical data that picked up along the way that was interesting.

If the source is a signal generator equipped with a circulator and
load, the generator is putting out 103 watts, and the circulator
load is dissipating 3 watts, is the generator still only putting
out 100 watts by definition?

Without sounding like too much of a wise guy, please explain the single electromagnetic pulse generated during a nuclear or other type of large explosion.

Does a certain degree of oscillation (ringing) occur to explain the vast distances travelled by what one would assume was a single large pulse?

Thanks Tam,

the tubing comes in 5m lengths - so I could cut one down to 3.3m and place it end-to-end with the remaining 5m tube. Then use the 1.7m offcut bolted to the underside of the 5m and 3.3m tubes. I could go to 30mm tube if needed. All I need now is the plans for the antenna but I should have those soon. I have some 25mm wide earthing strap I could use between the sections.

Richard;
I'm not sure if it does get 3 watts hotter. I was always under
the impression that operating a transmitter with a high reflected
power was unhealthy for my PA.

Anybody, such as an 18-year old Japanese student, can do it who can integrate the power radiated by each elemental length of wire over a surrounding sphere.

The radiation pattern comes out in the wash. It's an elementary matter. Hopefully you are able to do it for yourself.

It is likely Heaviside was the first, mostly in his head, but because it was so obvious he never bothered to write it down.

The Ph.D's of his age would have ridiculed the idea anyway on the grounds that some of his other more important work lacked rigor. MFJ-259B's and Viagra were yet to come.

There will be a big market is 'serious' amplifiers. BPL will be knocked for
a loop so often it will be rendered useless.

Not to mention the court cases that I HOPE will follow. We are the LICENSED
service.

One more thing. Remember the FCC and their decision to increase a owners amount of radio/tv stations he could hold? Well a committee in congress has put a kink in that plan.

I think we hams and other HF users should do the same thing. Write ALL your reps in congress. The FCC is obviously not qualified to do what it is doing. Anyone that even considers deploying BPL is braindead.

Wouldn't surprise me. The FCC requires the use of the least amount of
power needed to establish a given mode of communication. If BPM fills
the whole HF spectrum with S9-level fog, then QRP will go out the
door, and maximum-legal power will become technically necessary to
"burn through".

I'd hate that. So would our neighbors. Expect a big increase in
TVI/RFI complaints.

Similar things might happen with other licensed HF services... they
may also have to crank up their power.

Hi Bob,

my plan was to go with the fixed antenna, and let the motion of the
earth sweep out a path in the sky.

I'm still trying to figure out the frequency, and from that the size. I
was looking at RadioJove (http://radiojove.gsfc.nasa.gov/) and they use
a 7.09m simple dipole antenna to listen to radio storms from Jupiter. I
think, at least for my first experiments, I might try something in this
range. Eventually it would be nice to listen at 1420mhz, but from what
I've read simple dipoles aren't too good for high frequency signals. I
also checked out Mag-loop antennas, and they look pretty interesting. I
wish I could be more specific about my antenna plans, but my radio
experience wouldn't fill a 3x5 card. I think I'll start with a small
simple dipole, and just hook that up to my multi-meter to see what comes
over the line. but after that I think I might try a mag-loop, this place
(http://www.iri.tudelft.nl/~geurink/magnloop.htm) has a pretty good
howto. But, I need to do a bit of spectrum research, and see where I'm
most likely to find "natural" signals.

I'm planning on direct sampling. Since this project is all happening
under my wife's watchful eye, my funds are limited. If I can get my
hands on a cheap, low noise RF amplifier I'll go that way, otherwise, I
have a cookbook with some schematics I can copy. As far as the A/D
converter I was going to build something along these lines:
http://dbserv.maxim-ic.com/appnotes.cfm?appnote_number=151

thanks for all the info!

R.

I'm not that familiar with the atas antennas, but you might look at
some kind of ground -- a counterpoise wire(s), radials, whatever, to
replace the ground the car normally provides. I'm not sure the little
steel plate will be much of a ground. Maybe you can use it as a
gathering point for some radials.

I have put some thoughts on this stuff - about
RF radiation . Probably what is written in that
book is not correct - I found some other glitches
there as well.

I have tried to develop my own intuition about
radiation, and I've come up with this. What do
you think about the follwoing scenario :

The antenna (say dipole) is fed with some
electrical RF energy (voltage, basically). Take
a snapshot of the antenna when it peaks - say -
on its magnetic field (the two fields are 90 degrees
out of phase, in the case of a dipole). Now, what
would happen if we decouple the source of RF
energy at this moment? This field would collapse
creating some current in the antenna... and from
here we would experience amortized oscillations,
similar to those of an LC tank - no significant
propagation whatsoever !! However, we actually
do not interrupt the RF source. Then, this source
(changing its voltage) does exactly what the magnetic
field would do if was left alone : it creates the current
which would have been created by the magnetic field
otherwise. So, the magnetic field "has lost its job".
Well, now we should invoke the energy conservation
laws (I'm not an expert, but I know that "nothing gets
lost" when we talk about energy) which tells us that
we have some energy left in the magnetic field, energy
which has not done any "useful work" yet. Where does
this energy go?! Well, this "potentiality" manifests as a
propagated magnetic field: if some proper medium is
brought in its "relative proximity", the field will happily
collapse there and induce some current in that medium
(a receiver antenna - hopefully). It seems to me that
propagation in this sense is about manifesting some
spatial property at relative distance from the source -
say, a "proximity property".

Unfortunately I am missing something here, since
it seems that "the cooperation" bwetween the electric
field and magnetic field plays an important role in RF
radiation - and I don't know what this role is yet.

Please opinionate : does this get close to an intuition
about radiation? I am not a physicist , and I am not
even an alleged radio amateur (I can hardly call myself
a computer scientist); however, I am dead curious
about the matter.

Cordially,

Nic.

Message-ID: <oxHRa.247043$nr.9867522@twister.southeast.rr.com>
Source record: 112372

It helps me understand reflected power to think of a 50 ohm source of 10 volts connected to a half wave lossless line. In this situation the line can be removed from the equation and the load can be considered connected directly to the 50 ohm 10 volt source. If the load R is either a short or open circuit, there will be zero power transferred to the load, but there will be a big difference in the power dissipated in the source, two watts with the short and zero watts with the open.

If we bring the transmission line back into the picture, nothing changes, so the reflected power must be not be of any consequence as long as 1) the line is lossless, 2) we ignore transients, and 3) we do not use a circulator to separate the forward and reflected waves.

1) If the line is lossy, then the reflected voltage will not exactly cancel the forward voltage and there will be some power dissipated in the line from both the forward and the reverse waves.

2) If we consider transients, the initial conditions will be the same as if we connected a 50 ohm load to the source (instead of the short or the open). Things won't revert to the "line removed" case until the reflected wave reaches the input of the line. I'm not sure what happens to the reflected power. I'm guessing that is remains stored in the line until the source is removed and then (since the line is lossless) travels back and forth along the line forever. Since the voltage and current are 90 degrees out of phase, the stored power is purely reactive but could become real dissipated power if any resistance is reconnected to the line.

3) If we place a circulator at the line input, it's like connecting a 50 ohm load on the source i.e., it transfers 0.5 watts to the line and the reflected wave dumps the 0.5 watts into the circulator termination.

Any comments or corrections?

you have lowered the resonance of the system.. you will need to shorten the
antenna a bit to bring the swr down.. though 1:5:1 is not that bad.

>
> Bill W0IYH
>

This discussion assumes that we want the 100 W PA
to actually deliver 100 W to the coax. Assume a
Bird model 43 wattmeter in the line. If the PA is
actually delivering 100 W to the coax, then the
forward power must be 103 W and the reflected
power must be 3 W. The PA output power is
103-3=100 W. This is how we use the Bird
wattmeter. The Bird instruction manual tells us this.

Keeping everything simple and not getting into
peripheral issues is desirable at this point. For
example, a circulator will dissipate the 3 W, but
the above discussion does not assume a circulator.
The circulator's job is to force a 50 ohm load on
the PA, despite the fact that the coax input
impedance is not 50 ohms.

I'm dreaming of The ARRL Antenna Book, 15th edition, page 8-6. Spacing 1/8WL, phasing=135 deg, Gain = 4.1 dB. Remember, this is for two 10m verticals mounted in line with the vehicle, not one on each side of the vehicle. It is essentially a two element vertical beam with a cardioid radiation pattern and a large front/back ratio.

According to some posters, a source only puts out forward power minus
reflected power, by definition. 103W - 3W = 100W

Is it possible to build an omnidirectional receiving antenna with
gain?

Let us assume an ideal dipole Call it 0dBd

Now let us build two ideal dipole antennas and combine their outputs
we have an antenna with possibly twice the received energy or 3dBd
gain.

Now for signals from certain orientations we signals canceling in
phase for less than 0dBd gain....

Is it possible to build an antenna with more capture area, giving
gain,
without adding directivity?

Thought experiment saying it is possible......
Cover a 1 meter sphere with solar cells......

Cover a 100 mete sphere with solar cells......
It's clear that the 100 meter sphere would gther more energy than the
1 m sphere.... thus it seams it would be possible,

No what forms would an isotropic (Or at lease hemispherical) pattern
antenna with gain > 0 dBi look like?

The RF energy from the source accelerates and decelerates free electrons.
The changing energy levels of the free electrons causes the excess energy
to be radiated as coherent photons.

Not with a Norton source. :-) Quoting _Fields_and_Waves_in_Communication_
Electronics_, by Ramo, Whinnery, & Van Duzer, page 721: "It must be
emphasized, as in any Thevenin equivalent circuit, that the equivalent
circuit was derived to tell what happens in the *LOAD* under different
load conditions, and significance cannot be automatically attached to
a calculation of power loss in the internal impedance of the equivalent
circuit." Seems your above assertion violates that sage admonition.

Of course, the Aug. 2003 QST has some of them on page 19 & 108. The
Comet GP-24 for 2.4GHz is twenty end-to-end 1/2WL antennas.

If by omnidirectional you mean truly the same in all directions, up, down, and in azimuth, the answer is no.

Consider this. If you put 100 watts into a perfectly efficient antenna, 100 watts is radiated. If the antenna is omnidirectional (isotropic), the 100 watts is spread evenly out in all directions, and we can readily calculate the power density at any point in space:

Power density (watts/square meter) = P / A

where P is the power applied to the antenna and therefore radiated, and A is the area over which the power is evenly spread. The area of a sphere is 4 * pi * r^2, where r is the radius of the sphere (in meters, for power density in watts per square meter), so the power density from an isotropic source at any distance r is

P / (4 * pi * r^2)

So far, I haven't said a word about what kind of antenna is doing the radiating, only that it distributes the applied power evenly in all directions.

To get gain, you need greater power density for a given power input P at a given distance r (which is, in fact, the definition of gain). So what you need in order to get 3 dB gain is an antenna that, if you apply 100 watts of power to it, it radiates 200 watts.

When you figure out how to do that, let us know.

If you look into the meaning of "capture area", you'll soon find it's ham-speak for "effective aperture" which, for a lossless antenna, is the same as gain, and the same as directivity. So if two lossless antennas have the same gain, they have the same "capture area", regardless of their physical sizes or shapes.

Snarf wrote:
"Without sounding like too much of a wise guy, please explain the single pulse generated during the single electromagnetic pulse generated during a nuclear or other type of large explosion."

Can`t shed much light though my posting was referenced above.

Had a course in "Non-Sinusoidal Waveforms" 50-some years ago. It included finding sinusoidal constituents of various waveforms. A single bang event can excite resonances which decline a certain percentage of the remaining energy with each cycle. These are called damped oscillations. These can be generated by simply opening a switch.

But, I am ignorant of neuclear physics. Surely someone in this group has studied what makes lightning strike when an A-bomb detonates. All Hiroshima and Nagasaki meant to me was that I might soon be going home. I soon got to walk through Nagasaki before coming home. EMP was almost the least of the targets` problems. Over a large area, about all that was left standing were "fireproof" safes. Nagasaki`s 1940 population was 252,630. Its 1946 population was 174,141. The bomb dropped on August 9, 1945. We thought the Japs richly deserved what they got, and we all cheered when we heard the news. The life saved may have been my own. The bombs saved many more Japanese lives than they took.

The amazing thing is that the Japs hesitated after Hiroshima and the second bomb had to be dropped. It is tragically like the old Jack Benny joke when the mugger demands: "Come on now, your money or your life, what`s it going to be?" Benny replies: "I`m thinking, I`m thinking!"

The assumption that the source is outputting (forward power
minus reflected power) is essentially saying that all amplifiers
are perfectly matched and re-reflect all reflected power.
That seems like a stretch to me.

Message-ID: <vheok18dktkmc6@corp.supernews.com>
Source record: 112386

Sometimes "omnidirectional" means "equally radiating in all azimuth directions", which is the interpretation Cecil has used. In that case, yes, of course, you can achieve gain by concentrating the power in the vertical direction, i.e., increasing the power density at some elevation angles at the expense of others. A collinear antenna (linear antennas placed end-to-end as Cecil describes) is a common way of achieving that.

I inferred from the original posting that the intended meaning was truly omnidirectional, as in isotropic, the same in all directions in three dimensional space. If that's correct, the answer is no.

The explanation in my response was in terms of a transmitting antenna. It's well established (the reciprocity principle) that the gain of an antenna is the same for transmitting and receiving, so the conclusion is equally valid for a receiving antenna.

From the IEEE Dictionary:

"omnidirectional antenna - An antenna having an essentially non-
directional pattern in a given plane of the antenna and a directional
pattern in any orthogonal plane. Note: For ground-based antennas, the
omnidirectional plane is usually horizontal."

"isotropic radiator - a hypothetical, lossless antenna having equal
radiation intensity in all directions."

I agree equivalent circuits are invalid when it comes to calculating either efficiency or internal power loss. The circuit in my example was the ACTUAL circuit, i.e., a 10 volt source with a series 50 ohm resistor, not a Thevenin nor a Norton equivalent. With this restriction, I don't see anything wrong with my statement. Depending on what the ACTUAL circuit is in a power amplifier, I believe the current drawn can either increase of decrease when the load is removed.

Paul,
If you mean 'omnidirectional' in the commonly used
fassion of ham radio, then the answer is yes. If you
mean 'omnidirectional' as in an isotropic antenna, then
no. To date, and to the best of my knowledge, I have
never used an isotropic antenna, nor have I ever heard
one used. So, I guess the answer is yes...

I was implying iostropic in 3 dimensions....

Now for a paradox.....

If RX==TX as for as antenna gain

And 100W is 100W.... then isotropic had dBi =0 be the laws of
conservation of energy.....

No suppose we have an antenna that captures all of the energy passing
though a 1M square.......

Now make that a 10M square.....

Clearly a 10M "Fishing net" can capture more than a 1M net, but

Then RXgain != TXgain

So what gives where is this wrong?

Al,
If that 2 x 2 plate were sitting on the ground is might
be equivalent to the 'ground' furnished by a typical car
body. That's a long way from it being adequate if raised
above ground level such as in your attic. A car body, like
the 2 x 2 plate, is coupled to the 'dirt' it's on top of, and
which furnishes additional 'grounding' besides just the car's
body. A 2' x 2' metal plate laying on the ground ~may~ have
the same coupling that a car body raised 6-8" above ground
level.
(I have no idea if that's true or not, but I'm willing to go
along
with it.) But if you raise that car 10 feet off the ground, I
think the 'ground' furnished by the car's body will be quite a
bit 'less' than before you jacked it up. Same for the 2 x 2
plate. The plate should make a pretty good place to tie into
with a few radials/counterpoise'z, though. (But so would the
'pull-tab' from a Pepsi can, if you can solder to it...)

Ron, W4TQT wrote:
"Since the voltage and current are 90 degrees out of phase, the stored power is purely reactive but could become real diissipated power if any resistance is reconnected to the line."

Ron specified a "half wave lossless line" with complete reflection at each end.

Forward power into Ro creates a current in-phase with the voltage. Ro rigorously enforces it. An open or a short at the load end of the line creates a complete reflection in which the volts and amps are 180-degrees out-of-phase. The line again rigorously enforces it.

The only 90-degree phase angle is in the standing wave pattern.

Best regards, Richard Harrison, KB5WZI

The "pulse" is the envelope of the RF energy. Lots of frequencies more like
white noise actually, start suddenly, trail off not quite so quickly.
Similar to a radar pulse. Two things. RF, pulse modulated.
Omnidirectionally radiated. Does that help?

So that you could find the input impedance of the antenna with an
equation like the transmission line one? Zo=SRQT(L/C)? Using the
average Henries/m and Farads/m?

How do they measure a "surge impedance"?

Slick

Your sarcasm doesn't make your points as well as your logic.

How about this: An antenna is a transducer, and a transformer is
made up of two transducers.

So you need two antennas to make a transformer. And stick them
close together so they couple well, just for arguments sake.

Fair enough.

Shall i call this a Straw man argument? Or putting words in
someone's mouth?

Ok, an antenna is a transducer. But you can still optimize it for ERP, and that will depend on the impedance of free space or water or whatever. Why not throw out the whole concept of free space impedance if it doesn't matter?>

Actually, you are correct. I mis-quoted him somewhat. He calls
the radiation resistance of an antenna as the value of a ficticious
resistor that would dissipate the same amount of power that is
radiated by said antenna.

Wouldn't want to denigrate the reputation of a cool dude...

I looked over the insides of an SG-235 and initially thought it was capable of much higher power than the 200w rated SG-230 which I am very familiar with. Then I looked inside a Harris RF-382 series tuner rated at 500w like the SG-235. Either the Harris will handle several KW or SGC is stretching the ratings a bit.

From Don Johnson's, "40+5 Years of HF Mobileering." The Swantenna came in two models, the 45 and 55. They covered from 75 to 10-meters. On the less expensive one, you had to get out of the car and adjust the coil for each band. The more expensive one had a motor that could be controlled from inside the vehicle.

The antenna in question is a Swan Deluxe 742 Tri-Band Mobile HF Antenna. It covered 3 bands automatically. Swan sold this antenna to Cubic, who sold it to Barker and Williamson. The B&W number was 370-19.

It appears our remodel in our single-family home will have a number of fluorescent light fixtures.

Does anyone out there have these in your home and experience any noise that bothers your 160-10 m operation?

Should a new installation and new bulbs produce very little noise?

I would like to hear any experiences, including any work-arounds.

Regards,
Ted, K6KIM

SGC tuners are rated a bit over what they can handle with nearly
perfect antennas and grounds. If you push the envelope, count on
burning up relay contacts, and capacitors. I speak from years of
experience with their products in the commercial markets.

Feel free to call it what you want. I believe I've made as valid an
argument for an antenna being an automobile as you did for it being a
transformer, and based on the same criteria.

> Ok, an antenna is a transducer. But you can still optimize it for
> ERP, and that will depend on the impedance of free space or water or
> whatever. Why not throw out the whole concept of free space impedance
> if it doesn't matter?

The optimization of an antenna depends on many factors, only one of
which is the nature of the medium in which it's immersed. And among the
medium's important properties are its permeability, permittivity, and
the velocity of a wave propagating in it. The phase velocity and
characteristic impedance can both be calculated from the permeability
and permittivity, so you can't really say any one of these is more
important than the other.

It doesn't make any sense to throw out the concept of free space
impedance just because it confuses people who don't know what it means.

It's an extremely useful and well-understood concept. For example, reflection of a wave from a plane conductor or the ground can easily be found by calculating a reflection coefficient based on the impedance of the reflecting surface and the impedance of the impinging wave. (The impedance of a wave can be quite different close to an antenna than it is after it's traveled some distance.) If you look in some of those texts I recommended, you'll find the impedance of free space cropping up all over the place.

What needs to be thrown away is the belief that all impedances are the ratio of a voltage to a current, along with the notion that only resistors can have resistance.

>following: "It is a nonsense question that has caused nothing but
>misery".

Well said, Bill !

Every time that question is asked, this newsgroup goes into the same major convulsions. The same people produce the same arguments... and after a period of weeks to months, all the threads (they always multiply) grind to a halt from sheer exhaustion.

Nobody wins (though the last man left standing may think he has) because nobody has managed to convince anybody else to change his mind.

The innocent person who first asked the question has usually bailed out after the first three days. He just can't follow all the twists, turns and mistakes on both sides... but neither can anybody else, if truth be told.

Whenever someone asks that question, this newsgroup behaves like mice in a maze. We take different twists and turns each time, but overall, we always react the same. The perfect experiment!

Very few people seem to realise that the fault lies in the question itself. Any question that contains a built-in misconception can have *no* correct answer - except, "Sorry, that's not a valid question;" to which one might helpfully add, "What did you really mean to ask about?"

"Where does the reflected power go?" is even worse because it contains at least two built-in misconceptions: that reflected power waves exist, and that they have to "go" somewhere.

That question has *no* correct answer - and this newsgroup is living proof that none can be found.

(Douglas Adams' white mice must be absolutely delighted.... you know, the ones who are actually in charge of all this, running the whole planet Earth as a behavioral experiment. "Where does the reflected power go?" is their master stroke.)

In about as long as it takes to go to the 'VHF/UHF Long Yagi Workshop'
on the site below. Some other questions will be answered there too.

Certainly a shorter sub-boom centred on the balance point is one good
way to go. Another is to use quarter-inch larger square tube for the
middle section, with the inch-square boom running right through, and
hard aluminium shims driven into the end. Don't forget to use a larger
boom correction for that centre section.

I'd try one or the other. Attach a single 1/4 wave counterpoise wire
to the ground side of your antenna, and compare that to what happens
with the plate, by itself. In the past, in an apartment, I used a
short vertical with a loading coil, and tuned it by adjusting a single
counterpoise wire to 1/4-wavelength for the band being used. Worked
pretty good with 100 watts, tho' the wire was hot with rf :-)

Not really - "Him" will do nicely. Just spell his surname in capitals
:-)

Seriously, people like Terman, Kraus and Jasik do deserve our respect,
for developing textbooks that have become 'standards'. Over several
editions they have been subject to searching examination from thousands
of teachers and students, so there aren't many errors left in there.

That's the valid reason for using those names as touchstones. To
contradict one of those standard texts, you'd better have some good
arguments prepared.

- BUT -

Never quote a textbook as a substitute for doing your own thinking. That
is the ultimate disrespect to the original authors.

Hi Raphael

I doubt you'll see much on a multimeter by itself. Most measuring devices like that would have a hard time measuring AC past 20kHZ!

I think it was the Parkes radio telescope site (you know the movie "The Dish") that has a list of freqs used for radio astronomy. Be a handy place to start as you'd be able to avoid "human" band users. Sorry dont know the URL. It has "csiro" in it somewhere. I'm going to be driving past Parkes in a month or so. Might go have another look...

One of the nice things about magloops is their very narrow bandwidth. You may even be able to get away with a simple diode and capacitor detector. Kind of like an AM receiver (aka crystal set) but with a longer time constant so the DC voltage can be measured. You'll need an amplifier somewhere. I saw a magloop article with a built in preamp, cant remember where. If you are using a soundcard note that it will be AC coupled. ie wont be able to measure slow moving DC voltages. Back to an A-D converter or make up a voltage controlled oscillator feeding from the detector! (Noted the comment in the your other post. The sound card sampling rate isnt going to be so good for direct data capture. Hence my suggestion of the VCO)

Remember that a magloop bandwidth will be a percentage thing so if you go to high in frequency it may become too broad. Maybe the thing to do might be to build one on the Jove freq (abt 21.5MHz). Also protect the magloop tuning from the weather. Rain/changes in humidy will affect it and your measurements will change.

You might find it cheaper to build an A/D plugged into the parallel port. You could even write a 4 line DOS debug/bat script to read the port and dump the value to a file. Simple.. Only issue would be only 8 bits. From memory the port has 3-4 more control lines that could also be used for more. (Or get another printer interface card) I use to use a parallel port to drive a stepper motor and ez-al antenna for satellite tracking using the debug script method. Remember that the data acquisition speed deosnt need to be fast. (ie more $$$)

Okay good luck!

Cheers Bob

For what it's worth, My 2 meter J-Pole is up about 30 feet and encased in a PVC pipe. It handles 50 watts (nominal) with no problems for the last 10 years.

YMMV

There's a much easier solution!! Have the FCC propose a rule that
communication receivers cannot have receivers with sensitivity lower
than 50 microvolts!

If 60 dB noise levels are real an amplifier won't help me hear the weak
ones! So, simply eliminate the ability to hear the weak ones and we will
all be happy, NO? It's much easier to install a 60 dB pad on a receiver
than pushing amplifiers and Long John Yagis. Hmmm ... ;-)

> transistor linear HF PA, makes no mention of Rg.

Amen, brother. I was thinking after making my last posting to this
thread that the one thing I DON'T bother thinking about when designing
a PA is what source impedance it will present. I worry about
currents, voltages, efficiency, distortion, a network to present the
proper load to the active device(s)... but not Rg.

In precision instrumentation systems, the output is commonly levelled
or monitored through a levelling splitter (not to be confused with a
power divider), so that a virtual zero-impedance point can be
established, with a 50-ohm (or other Zo) resistor from that point to
each output. And network analyzers are commonly calibrated with
precision loads so that the imperfections in their outputs and
reflectometers and cabling can be backed out by the calibration
software.

Cheers,
Tom

Shoot, propose simultaneously that hams be allowed 50 kilowatts output.
Not that either of these are remedies for the potential problem but
maybe it will help the FCC understand whats going on.

Hi, I re-designed a 8 el. Quagy for 70cm because I had problems with the original design. I thought it might interest to someone so I put it on www.qsl.net/ik1hge/homebrew/homebrew.html
It seems that the antenna works fine (gain looks outstanding for such a small antenna, but I can't measure it accurately), however I'd like to get some feedbacks from someone else. It's very easy to build.

Thanks
Bye

I guess it may depend to some extent on the quality and type of
fixtures/bulbs
that you install.

My shack is in a finished "walk-out" basement (the house is dug into
the slope at the top of the hill, such that from the front it appears to
be a 1-story structure, but from the back side, it's 2-story).

The entire basement area, ham shack, electronics lab, office, family room,
woodshop, etc. is VERY well illuminated by an array of fixtures set in the
grid of a suspended ceiling. Area is about 2000 sq. ft. and there are 14
4 ft., 4-tube fixtures.

I have checked and I can't see a noticable change in RX noise in the HF
bands between all lights off and all lights on.

If you get a tube that's starting to go, or a bad ballast, that could cause
a dramatic change ... something that bodes in favor of replacing bad
tubes.

(Of course, my antennas are outside, away from the lighting, and the
house is covered with aluminum siding for low maintenance, which
may help to contain any noise from the lighting ... YMMV, depending
on such shielding, antenna placement relative to the lighting, etc.)

I agree. The gain measures the "performance difference"
between a directional antenna and an isotropic one. Since
the isotropic antenna is a reference point, the gain can
not be more than zero. You can experience loss though,
by badly designing your omnidirectional antenna.

When I switched to #14, the impedance did not change more than a few tenths
of an Ohm. However, resonance went down about 10 KHz.

BTW, when I took my first Junior level EE Fields & Waves course I asked my
prof about the same question that Slick brought up. Was convinced that 300
Ohm TV antennas were really 377 Ohms!

Any transducer I can think of offhand converts between mechanical energy and electrical energy, as for instance a loudspeaker, microphone, mechanical filter, etc.

As for the impedance of free space, one way to build a stealth aircraft is to cover it with material that has a resistivity of 377 Ohms/square. Then there is no reflection

That would depend on the output impedance of the transmitter. If it is 50
Ohms, all the reflected power would be absorbed by the transmitter. If it is
0 Ohms or its Norton equivalent, it is all reflected, and none is
dissipated.

This whole discussion points out the fallacy of trying to understand
reflections by sending a CW signal. Consider a 100W pulse radar transmitter.
Also, assume the transmitter rurns off between pulses (a good assumption),
and that the antenna mismatch causes 3% of the power to be reflected.

When the pulse reaches the antenna, 97W is transmitted, and 3W is returned.
All of this 3 W is reflected by the transmitter, and a second pulse is
produced where 2.91W is radiated and .09 W is reflected back. This is
re-reflected, and a third pulse is produced where .0873 W is radiated and
.0027 W is reflected, etc, etc.

Yes, it does help. It helps to disprove that one wave does not push the preceding wave along. Each is an independent event which does not interact with other waves from the same source until a boundary or other interface is encountered, resulting in interference patterns. Then they will affect each other, both positively and negatively, regarding amplitude.

Steve,

Here is something else you might want to do. I did this to a KLM50-7 which has a boom a bit less than 7 meters long. Took 2 pieces of 3/8 inch Al tubing, about 5 feet long, and flattened both ends in a vise, then bent at 45 degrees. Drilled holes in the flattened portion, and bolted one end of each to the boom, the other end to the mast through one hole, and a long bolt, about 3 mm. Makes the boom absolutely stable in a wind.

There is nothing wrong with considering the
steady-state solution. We do that all the time.
The steady-state is achieved mathematically by
considering an infinite sum of forward and
reflected waves (for a CW signal) until it
converges to a steady state. In the final solution
the source impedance is found to have no effect on
the standing wave pattern (the SWR).

Reference: W.C. Johnson "Transmission Lines and
Networks", McGraw-Hill 1950, chapter 4, Equation 4.23.

In the steady state the final result is according
to my discussion.

Source record: 112337

Among the numerous effects of a nuclear explosion in the atmosphere are X-rays and Gamma Rays. These are photons of two greatly different wavelengths. These photons interact with the atmosphere in a very complex manner depending on the frequency of the photons. Narratively, these can be thought of in the following way.

The atmosphere absorbs the photons. The energy in the photons causes ionization of the air molecules, primarily Nitrogen and Oxygen. The ionization strips the electrons off of these molecules. This leaves the nucleus positively charged and creates an electron shower that blasts away from the nucleus.

So, the electrons, being much lighter than the nucleus, move further away from the nucleus causing a electromagnetic wave. There is a time varying electric field between the nucleus and the electrons: and, the motion of the electrons creates a simultaneous time varying magnetic field. The electrons 'curve' back to the nucleus to recombine and produce no net charge in the time period of 10s of microseconds after the nuclear event.

Now, the X-rays are absorbed by the atmosphere over the distance of several meters from the blast source. While the Gamma rays are absorbed over the distance of several kilometers. X-rays and Gamma rays travel at the speed of light so the resulting waveform of the EM field has a very fast rise time from the X-rays, a longer rise time for the Gamma rays and a slower fall time from the Gamma rays.

The EM Pulse has a very fast rise time, typically less than 10 nanoseconds [10 MHz], and a longer fall time typically 10s of microseconds [< 1 MHz]. A Fourier analysis of the frequency components shows the EM energy ranges from 100 KHz to in excess of 200 MHz.

So, the resulting EM wave then can propagate in accordance with the characteristics of the Low Frequency, Medium Frequency, High Frequency and Very High Frequency propagation characteristics in effect when the explosion occurs.

Unclassified data indicates the EMP Pulse has field intensities in excess of 25,000 volts per meter in the HF portion of the spectrum! [Hmmm ... a ten meter dipole antenna could be in an EM field in excess of 125,000 volts!! WOW! Talk about ESD susceptibility with the new IC 746 Pro. Not much would survive this unless specifically designed to do so.]

This is a far as I'll go with the explanation.

Deacon Dave, W1MCE

PS: The Rev. Deacon spent many years designing equipment to MIL Specs
including nuclear effects.

The only application that I have seen in which this was true
was the so-called Rectenna - an array of low-gain dipoles,
each of which had a diode detector at its feedpoint terminals.
The direct-current diode outputs were summed to produce the
"signal" which was more-or-less proportional to the area of
the array. But the array itself had very low directivity -
pretty much that of a single dipole element - making it
unnecessary to beam-steer it.

This was proposed as the Earthside end of a space-based power
satellite system that would convert sunlight in geosynchronous
orbit to microwave energy and beam it down to the rectenna. There
it would be "detected" to DC which would then be converted to
60-Hertz HV sine waves for injection into the power grid.

The thing that makes this work was, of course, the non-linear,
non-coherent rectification process at each array element. And
it only works for DC. If a higher-bandwidth modulation is
imposed on the RF energy, a point is reached due to travel-time
delay where the detected signal at one end of the array is out
of phase with that detected at the opposite end. If synchronous
detection is attempted, the highly undesireable array directivity
is immediately restored - much to the chagrin of the system designers.

Tin a file and use that to do the scratching. Works for bigger
stuff. Makes a better contact. Seal the joint from the weather
or you may get bad electrolytic corrosion at the joint.

Hi Tam,

That material has been around for a couple of decades, but is quite
heavy. You might find yourself with a fleet of stealth bumper cars as
a result.

Hi All,

Such easy things to confirm.....

I have a pair of Pioneer speakers, looked at their spec.s pasted to
the back, rated flat from 10Hz to 25KHz (flat being order of two from
nominal 10 Ohms) with a small (BW) peak at 80Hz.

Years ago in my metrology lab, we abandoned laboratory grade
amplifiers and speakers for commercial ones as the market offered far
better product at much cheaper rates.

Sound, like light, makes virtual experts of everyone through their
misperception of its common features. Eyes and ears are fine
instruments clouded by the brain.

TV transmitting antennas are generally omnidirectional, and have gain. They do this by concentrating all energy along the horizon. In fact, some work so well that they put up a secondary antenna at 100ft or so to take care of people who live close by.

If you want to talk about practicality, it would be easy to build one at 2 meters. Forget about it on 160m.

Hi Tom,

H.W. Bode describes these characteristics through "Noise" Gain. It is
that portion of the "Open Loop" gain (or GBWP) that is returned to the
input.

The amount of "Noise" Gain is directly responsible for the significant
benefits (control over) of:
Input Impedance;
Output Impedance;
Noise (within the system);
Linearity (distortion);
Phase Response;
Gain variation;
Stability;
Frequency Response.

Hi Tam,

This is painfully obvious. It is also painfully demonstrative. It
also appears to be painfully avoided in lieu of providing an actual
value (Punchinello seems to wholly ignore his own cries that lacking
numbers renders such whining as ignorance).

I've read for years that the common RF rig is NOT a 50Ohm source, and
absolutely none dare commit themselves to just what value it is (much
less offer their own measure). Being a physical reality, the rig must
present some real value, but vacuous theory seems to bar that
discussion.

It would be a vertical beam with the boom (vehicle) capacitively
coupled to ground. It would work best on 10m-11m but should work
pretty well all the way down to 14 MHz. Probably not very useful
except for stationary use.

Actually, I experienced the same effect from a rear bumper mounted
screwdriver on my pickup. At the frequency where the truck is 1/4WL,
I experienced considerable gain in the direction the front of the
truck was pointed compared to off the sides of the truck. On one
Alaska contact from Arizona, it made the difference in being able
to carry on a QSO or not. It was a V-beam effect.

Dr. Slick wrote:
> How do they measure a "surge impedance"?

For a transmission line, it is the same as the characteristic impedance. For a traveling wave antenna, it is the same as the feedpoint impedance. So for a center-fed standing wave antenna, like a dipole, you could terminate the ends of the antenna to eliminate reflections and then measure the feedpoint impedance.

Standing wave antennas are like transmission lines with standing waves. The impedance at any point is the (forward voltage wave plus the reflected voltage wave) divided by the (forward current wave plus the reflected current wave). The feedpoint impedance of traveling wave antennas is usually about 600-800 ohms according to The ARRL Antenna Book.

I agree, Roy, but what can we do about it? I had been using "virtual impedance" to differentiate a voltage to current ratio from an intrinsic physical impedance. How would you differentiate an intrinsic physical impedance from a voltage to current ratio?

Hi All,

My situation is very similar to Carl's, and my experience is very much
like his as well.

I went a little further to provoke problems to confirm all sources of
noise within my home.

The first was to establish a noise baseline (done at various times of
day and night and time of year, across the many bands) by using my rig
on battery power (it is actually always battery powered, but employs a
floating charger) with the charger and all accessories disconnected

and ground removed (no ground loops). I also throw the main breaker. There are any number of hidden power loads that you cannot disable or otherwise isolate. One of the most egregious examples is the doorbell transformer that in older homes can turn into an S9 noise generator that will plague many "experts."

That was Step One. There is not much point in going to Step Two if you cannot isolate sources. Many succeed however, through weeks of hair pulling and a magical connection (or break) that could also kill them.

Step Two is to throw the breaker back on. If this seems a huge chore of having you go through the house resetting clocks, let me console you with the evidence that that end of the gene pool has been thinned out considerably by the twice annual event of daylight savings and the invention of the digital clock. Survivors of that Darwinian task can now take another noise reading (again observing the list of times and frequencies already mentioned).

Step Three (this is a progression back toward your conventional shack design) is to start adding loads to the house circuit. Again, take readings (you need not note times as you are now introducing correlated noise). Remove power from all such loads.

Step Four is to add back your conventional ground (that is, the ground through which power, not RF arrives). This introduces the possibility of a ground loop. Repeat Step Three.

Step Five is to add back your conventional accessories. This too introduces the possibility of a ground loop. Repeat Step Four (which recursively repeats Step Three, of course).

All told, this should result in a grid of readings with several dozen (maybe 100) data points. This will take far less time than trying to solve a noise problem that persists for more than a day (and possibly on the WRONG day).

Any one of these tests could result in the appearance of noise. Sometimes this is correlated to the last addition of a load, but as tantalizing as that is, it too refuses cure (and you cannot live without that load).

Such problems then need to be isolated as to being over the air, or through conduction.

Over the air problems are often fixed by Carl's observation of having the antenna away from the house. More telling is the addition of a choke BalUn at all feed points (even those remote from the house, this is especially true for long wavelengths).

Problems of conduction are in fact ground loop based. You are sharing the same circuit as the noisy load. I have fluorescents above my station, and dimmers on every incandescent bulb in my house and yet I

suffer very little noise arriving by conduction (and find it perturbs over the air by 3 or 4 dB above baseline before I go turn off that light I rarely do that because atmospherics and remote noise often overwhelm this local contribution).

A simple way to confirm this noise path is to break it by powering your equipment off another circuit (circuit meaning the wire path to a separate breaker at the distribution panel). This can make 10-60 dB difference for dimmers alone (or the other killer, the fish tank heater). Simply employ a sufficiently long extension cord so that you do not change your shack configuration (which would also force another baseline evaluation).

The single next greatest contributor of noise is through peripheral, accessory connections. The lighted Daiwa SWR meter has a lump you plug into the wall. Both the lump and the connection are potential problems if you disregard them and one or the other turns out to be the problem. It is easy to disregard such an inconsequential item, so to are computers with modems the third most common source of ground loop.

If you wish to preserve those accessories, buffer your power through an isolation transformer with a faraday shield connection. Connecting the shield is also not obvious (there are reasons to connect it to the sink, there are reasons to connect it to the source - but never both). My battery charger is so buffered.

Well, these are the heavy hitters of noise. There are more, but their application becomes a matter of simple logic and practice when you have a basis.
